Severe malaria is almost always caused by P. falciparum, which, because of its ability to infect erythrocytes of all ages, can produce very high levels of parasitemia. Cerebral malaria is the most common clinical presentation of severe malaria. Many factors can contribute to diminished brain function in severe malaria, including obstruction of microvascular flow, elevated intracranial pressure, cerebral edema, disruption of the blood–brain barrier, hypoglycemia, hypovolemia, and seizure activity.
Obstruction of microvascular flow is caused by sequestration of erythrocytes in brain capillaries, autoagglutination, and decreased erythrocyte deformability caused by intracellular parasites. Cytoadherence, a process in which \textit{P. falciparum} derived proteins on infected erythrocytes attach to the CD36 receptor on vascular endothelial cells, appears to mediate sequestration \cite{84}.

In endemic areas, malaria is largely a disease of children. By the time they reach adulthood, residents of endemic areas develop partial immunity to \textit{Plasmodium} infections, limiting the severity of disease. Travelers, conversely, are generally not immune; nonimmune adults who become infected are almost always symptomatic, and severe disease may develop.

\section*{Diagnosis}

\subsection*{Clinical Features}

Although imported malaria may occur at any time after leaving an endemic area, there are epidemiologic clues to help guide the evaluation. Among returning travelers presenting with fever, the most common specific diagnosis is malaria, occurring among 9\% of cases \cite{85}. Among cases diagnosed in New York, 80\% of patients had symptom onset within 1 month of leaving the endemic area. Most of the cases presenting later than 1 month postdeparture had \textit{P. vivax}, which rarely causes life-threatening disease.

Patients with malaria present with a history of fever and chills, but fever may not be present at the time of the initial examination. The classic descriptions of tertian and quartan fever are rarely seen; their absence is not evidence against the diagnosis of malaria. Chills, headache, fatigue, and myalgias are common complaints. Signs include hypotension, jaundice, and hepatosplenomegaly, but these are seen in a minority of patients \cite{86}. If hypotension is present, gram-negative bacteremia must be excluded and treated empirically until cultures return. Cough, dyspnea, and tachypnea may dominate the clinical picture in children, causing confusion with pneumonia in areas of the developing world where chest radiography is not readily available \cite{87}.

Malaria during pregnancy presents with similar, although more severe, manifestations. Hypoglycemia and lactic acidosis are more frequently seen in maternal malaria, and the mortality of cerebral malaria is increased \cite{88}. The partial immunity of residents of endemic areas is blunted during pregnancy \cite{89}. Other complications include preterm delivery, intrauterine growth retardation, anemia, postpartum hemorrhage, and eclampsia \cite{88}. Human immunodeficiency virus (HIV)–infected gravida are both at increased risk of infection with
Plasmodium species, and have a more severe course of malaria. Additionally, malaria is associated with an increased maternal HIV viral load, and may increase HIV transmission to the fetus [90]. Placental malaria may be present even if peripheral blood films are negative for parasites [91].

Complications

The most common complications of malaria are cerebral malaria, severe anemia, metabolic acidosis, and noncardiogenic pulmonary edema. Gram-negative sepsis is a less common, but potentially grave complication of severe malaria.

Variability of host susceptibility and of the definition of cerebral malaria may account for the wide range of reported incidence. The World Health Organization (WHO) defines cerebral malaria as coma that cannot be explained by hypoglycemia, postictal state, or other nonmalarial causes, such as sedative drugs, for a patient with parasitemia. Common findings are decerebrate or decorticate posturing, flaccid tone, seizures, and retinal hemorrhages. A recent study of imported severe falciparum malaria reported cerebral malaria in 37% of cases [92]. Overall, mortality of severe malaria in that series of cases treated in a highly experienced intensive care unit setting was 11%. Cerebral malaria was present among 90% of nonsurvivors.

Laboratory Features

Common laboratory findings are anemia, thrombocytopenia, and hyperbilirubinemia. Hypoglycemia, elevated creatinine, and hypotherbinemia may also be present [92].

Microscopic examination for parasites on thick and thin films of peripheral blood remains the standard for diagnosis of malaria. Sensitivity is increased when blood for malaria smears are obtained from a capillary-rich area, such as the fingertip or earlobe, rather than by venipuncture. A thick smear examined by an experienced microscopist can detect 50 parasites per μL of blood, which is equivalent to 0.001% of erythrocytes infected [91]. Sensitivity is approximately 10-fold lower for routine clinical laboratories. In addition, patients with falciparum malaria may have parasites sequestered in deep capillaries of the spleen, liver, bone marrow, or placenta, with a false-negative peripheral smear. Because the sensitivity of the smear is imperfect, empiric therapy for malaria should be administered when clinical suspicion is high. The thin blood film is used to identify the species and to quantitatively follow the parasitemia on serial samples. Real-time PCR is more sensitive than microscopy, especially at low levels of parasitemia, and although it is not
Food and Drug Administration (FDA) approved, the assay is readily available from reference laboratories. The CDC currently encourages specimens from confirmed cases of malaria diagnosed in the United States to be submitted to their laboratories for PCR testing for species confirmation and antimalarial resistance, for surveillance purposes [93]. Many rapid diagnostic tests (RDTs) have been developed which detect *Plasmodium* antigens and may provide a rapid diagnosis of malaria when access to high-quality microscopy is not readily available, although these tests do not provide information regarding species or degree of parasitemia; currently, only one RDT is approved for use in the United States [94].

---

### Differential Diagnosis

Cerebral malaria may mimic meningoencephalitis owing to viral, bacterial, fungal, or other parasitic causes. Dengue, typhoid, *Rickettsial* infection, or mononucleosis may present with an undifferentiated fever in a returned traveler. The differential diagnosis of jaundice in this population includes leptospirosis, yellow fever, viral hepatitis, sepsis, and relapsing fevers [87]. Bacterial sepsis must also be considered as a separate or a complicating diagnosis.

### Treatment

Management in an intensive care unit is indicated for patients with severe malaria. Careful management of fluids and electrolytes is critical, as well as monitoring for hypoglycemia. Renal, cardiac, and neurologic function should also be carefully monitored.

Intravenous quinidine has been used in the United States for the treatment of severe malaria since 1991, when the CDC stopped providing intravenous quinine [95]. At that time, quinidine was readily available on most hospital formularies, and therapy could be initiated rapidly. The declining use of intravenous quinidine for cardiac dysrhythmias has reduced the ready availability of quinidine, but a replacement strategy has not yet been developed for malaria [96], and it remains the drug of choice. It should be initiated for severe malaria, defined as a positive blood smear with any one of the following criteria: impaired consciousness/coma, severe normocytic anemia, renal failure, pulmonary edema, acute respiratory distress syndrome, circulatory shock, DIC, spontaneous bleeding, acidosis, hemoglobinuria, jaundice, repeated generalized convulsions, or parasitemia greater than 5%.
Hypoglycemia, QT interval prolongation, cardiac dysrhythmias, and hypotension may complicate quinidine infusion. Intensive care unit monitoring and consultation with an infectious disease specialist and a cardiologist are recommended. Cardiac complications may require slowing or stopping the infusion. When dosage is calculated, it is important to distinguish the salt from the base to ensure accuracy. The usual dose is 6.25 mg base per kg (10 mg salt per kg) loading dose intravenously over 1 to 2 hours, then 0.0125 mg base/kg/min (0.02 mg salt/kg/min) continuous infusion for at least 24 hours. If the patient has received mefloquine or more than 40 mg per kg of quinine in the 12 hours prior to beginning quinidine infusion, the loading dose should be omitted. Dosage adjustment for renal failure is not necessary during the first 48 hours of therapy [97]. Thin smears to assess the degree of parasitemia should be performed every 12 to 24 hours. Oral quinine 542 mg base (650 mg salt) three times daily for 3 to 7 days should be substituted when the patient is able to swallow, parasitemia is less than 1%, and mental status is normal. For infections acquired in Southeast Asia CDC recommends that therapy continue for 7 days; for disease acquired in Africa, therapy should be stopped after 3 days.

Patients with malaria normally show improvement in 1 to 3 days [98]. If the course is more prolonged, drug resistance or inadequate serum drug levels should be suspected. In addition to quinine, the patient should be treated with one of the following: doxycycline 100 mg orally twice daily for 7 days, tetracycline 250 mg four times daily for 7 days, or clindamycin 20 mg base/kg/d orally in three divided doses for 7 days.

Artesunate, a new agent that was developed in China, has been shown in a randomized controlled trial to be superior to quinine for therapy of severe malaria [99]. Although it is not FDA approved for use in the United States, it is available on a treatment investigational new drug protocol from the CDC for cases of severe malaria. Physicians who encounter a case of *Plasmodium falciparum* malaria should contact the CDC malaria hotline (770-488-7788) to report the case and to obtain artesunate; parenteral quinidine (in combination with doxycycline, tetracycline, or clindamycin) should be initiated while awaiting artesunate. If quinidine is not on the hospital formulary, the hospital pharmacy should attempt to obtain it from a nearby facility.

Treatment of a pregnant woman with malaria requires additional considerations [88]. High doses of quinine are reported to be abortifacient. Nevertheless, treatment with quinine has not been associated with an increased risk of congenital abnormalities, low birth weight, or stillbirth, and it is considered to be safe in the first trimester [100]. As discussed earlier, quinidine is substituted for quinine in the United States. Quinidine is listed as category C and is considered safe for breastfeeding women. Clindamycin should be given in conjunction with
quinidine or oral quinine treatment [94]. Chloroquine is safe for use in pregnant women for the treatment of non-*falciparum* or chloroquine-sensitive *falciparum* malaria. Artesunate-atovaquone-proguanil has been shown to be superior to quinine during the second and third trimesters, with no differences in birth weight, duration of gestation, or congenital abnormality rates in newborns [101]. If fetal distress is observed on monitoring, emergency cesarean delivery may be necessary [87,102].

Exchange transfusion is controversial owing to the lack of randomized trial data. Although its use was previously recommended by the WHO and CDC for patients with severe disease [87], a recent retrospective propensity score-matched study of patients with severe malaria reported to the National Malaria Surveillance System revealed no survival benefit of exchange transfusion [103]. Although some still advocate for its use in cases of severe malaria [104], the CDC has since revised its guidelines and currently does not recommend using exchange transfusion as an adjunct therapy; the WHO also does not make any recommendations regarding its use [94,105].

A randomized controlled trial has shown that corticosteroids were of no benefit and potentially harmful in the treatment of cerebral malaria [106]. Other adjunctive therapies that should not be used include heparin, sodium bicarbonate, mannitol, immunoglobulins, and iron chelators [87,106].

Advances in cerebral malaria, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 74.2.

### TABLE 74.2 Summary Recommendations for Management of Cerebral Malaria Based on Randomized Controlled Clinical Trials

- Corticosteroids are harmful and should not be used.\(^a\)
- Artesunate is the antimalarial of choice for cerebral malaria. When it becomes available in the United States, it should replace quinidine for this indication. Physicians who encounter a case of cerebral malaria should contact the CDC for an update on availability of aretsunate.\(^b\)

---

CDC, Centers for Disease Control and Prevention.
ROCKY MOUNTAIN SPOTTED FEVER

RMSF is a potentially fatal zoonosis caused by the bacterium *Rickettsia rickettsii*, which is transmitted by ticks. Although the classic constellation of findings is fever, rash, and tick bite occurring in the summer months, it is important to consider the disease even when some of these features are lacking. A history of tick bite is reported in only 60% of documented cases [107], and rash may be absent in 20%. Recognition of RMSF is critical, because outcome is much improved with timely, appropriate therapy [108].

RMSF is transmitted by the hard ticks *Dermacentor andersoni*, *Dermacentor variabilis*, *Amblyomma cajennense*, and *Rhipicephalus sanguineus*. The latter tick, previously a recognized vector for RMSF in Mexico, was implicated in a recent outbreak of RMSF in Arizona, an area that had previously been spared this disease. A review of cases of RMSF that were reported to the CDC’s National Notifiable Diseases Surveillance system from 2000 to 2007 revealed a greater than fourfold increase in incidence over this time period, although the majority of reported cases were probable, rather than confirmed cases, and a change in case definition in 2004 to allow the use of enzyme-linked immunosorbent assay tests in the reporting of probable cases is postulated to have contributed to this increased incidence [109]. Yet, another change in case definition and reporting standards occurred in 2010, such that RMSF is reported along with other clinically similar *Rickettsial* infections as “Spotted Fever Rickettsiosis,” which may influence future surveillance reports [110]. Although the peak incidence is in the summer months, cases occur throughout the year. Classically, it has been considered that children and males are at highest risk, but recent CDC data show that females and adults have only a slightly lower incidence. Native Americans have a higher incidence than other ethnic groups. RMSF was first described in Montana, thus its name, but is more frequently seen in the Southeastern United States, especially the Carolinas, Oklahoma, Arkansas, and Missouri.

Pathophysiology

*R. rickettsii* parasitize endothelial cells of many organs and vascular smooth muscle. The organisms cause a direct cytopathic effect, leading to vascular injury, clotting activation, and a vascular leak syndrome. In
severe cases, this manifests as multiorgan failure. Renal failure, respiratory failure, and coma may ensue.

**Diagnosis**

**Clinical Features**

The presentation of RMSF is protean, owing to the multisystem nature of the disease. Symptoms include fever, malaise, headache, rash, myalgia, nausea, vomiting, abdominal pain, and diarrhea. Two-thirds of cases have a temperature above 102°F at presentation; 90% have temperature above 102°F within 48 hours of presentation. Rash generally appears by the second or third day of illness and classically starts at the wrists and ankles, but is frequently generalized. It may involve the palms and soles; the face is spared. Rash may be missed in persons with dark skin. Gastrointestinal symptoms may be prominent, despite the systemic nature of the disease. Headache is typically present and is often severe. The key to the diagnosis is to consider it in any febrile patient who has been spent time outdoors in an endemic area. Investigations into the Arizona outbreak which reviewed 205 cases that occurred in multiple tribal Native American communities between 2002 and 2011 revealed that cases occurring in this region were more often atypical in presentation, and case fatality was higher, than cases reported from other regions in the United States [111,112]. Thus, clinicians practicing in this region should remain vigilant about the possibility of RMSF in febrile or otherwise ill-appearing patients and institute empiric treatment promptly.

**Laboratory Features**

Laboratory findings include a white blood cell count that is typically in the normal range, although a manual differential count reveals a shift to immature neutrophils. Platelets are usually decreased. Other nonspecific findings reflect the multisystem nature of the process and include hyponatremia, elevated creatine phosphokinase, hepatic transaminases, and creatinine and clotting indices (prothrombin time, partial thromboplastin time, and fibrin degradation products). CSF examination commonly demonstrates a mononuclear pleocytosis and, occasionally, an elevated CSF protein and low CSF glucose levels [108].

**Differential Diagnosis**

*R. rickettsii* cannot be cultured in most clinical laboratories; therefore, the diagnosis is most often based on clinical grounds. Diagnosis may be
confirmed by biopsy of skin involved with rash and processed with immunofluorescence or immunoperoxidase staining or by PCR. Confirmation can also be made by serologic testing of acute and convalescent serum, 2 to 4 weeks apart. These methods usually provide retrospective confirmation of the diagnosis, and although this is important for accurate epidemiologic surveillance, these tests do not help in clinical decision-making at the point of care. A single elevated immunoglobulin M (IgM) antibody titer is likely not helpful, either, because false positives can occur [113].

Differential Diagnosis

RMSF is frequently misdiagnosed as pharyngitis or scarlet fever, despite the low incidence of sore throat [114]. Gastroenteritis is also a common initial diagnosis, owing to prominent gastrointestinal symptoms. RMSF must also be distinguished from rheumatic fever, encephalitis, meningitis, pneumonia, measles, meningococcemia, leptospirosis, acute abdominal illness, idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, drug reaction, ehrlichiosis, and vasculitis [108,114,115].

Therapy

Specific therapy should not be delayed while awaiting confirmation of the diagnosis. Most broad-spectrum antibacterial agents such as cephalosporins, penicillins, and sulfa drugs are inactive against R. rickettsii. The treatment of choice for nonpregnant adults and children weighing more than 45 kg is doxycycline [116], 100 mg twice daily for 7 to 10 days. Children who weigh less than 45 kg should be given 2.2 mg per kg twice daily [107,117]. The risk of dental staining by tetracyclines in children is small for short courses of therapy; this consideration should not delay treatment [118]. A recent retrospective cohort study of children on a Native American reservation in Arizona who were treated with doxycycline for RMSF when they were less than 8 years of age demonstrated that these children had no differences in dental staining or enamel hypoplasia, compared to other children in the same community who did not have doxycycline exposure [119]. Therapy of pregnant women is problematic because tetracyclines are associated with maternal hepatotoxicity and fluorescent yellow discoloration of fetal deciduous teeth. Calcification of permanent teeth does not begin until after birth; discoloration of permanent teeth would not be expected. The US FDA and the Australian Drug Evaluation Committee have assigned pregnancy category D to doxycycline. Chloramphenicol is considered pregnancy category A by the Australian Drug Evaluation Committee [120]. Although teratogenicity has not been proven with chloramphenicol, maternal
aplastic anemia or reversible bone marrow suppression may occur. Gray baby syndrome has occurred in neonates treated with chloramphenicol, and may occur in infants born to women treated with chloramphenicol near term. Doxycycline may be used for women presenting with RMSF near term [121]. Most authorities recommend therapy of pregnant women in the first or second trimester with chloramphenicol, 50 to 75 mg/kg/d in divided doses. Corticosteroid therapy has not been studied in a controlled manner, although older literature has recommended it for patients with widespread vasculitis and encephalitis [122].

Prognosis

Outcomes are directly related to timely, appropriate therapy. Mortality rates are as high as 20% for untreated cases, and 5% with proper therapy [123,124]. Risk factors for mortality include central nervous system involvement, renal dysfunction at presentation, a delay in the institution of therapy, therapy with an agent other than a tetracycline [116], and increased age.
MISCELLANEOUS INFECTIOUS DISEASES

There are many unusual infectious diseases that occasionally lead to intensive care unit admission. Several of these diseases are discussed briefly below and others are discussed in other chapters, such as serious epidemic viral pneumonias (Chapter 83) and biologic agents of mass destruction (Chapter 130).

Ehrlichiosis and anaplasmosis are tick-borne Rickettsial diseases that present as a fever with few localizing symptoms or signs. Headache, myalgias, malaise, and rigors are seen in nearly all cases; gastrointestinal or respiratory symptoms may occur in a minority of cases [125]. Human monocytic ehrlichiosis (HME), caused by Ehrlichia chaffeensis and transmitted by the Lone Star tick (Amblyomma americanum), is most commonly seen in the Southeastern United States. HME may present with meningoencephalitis, acute respiratory distress syndrome, and a toxic shock–like illness [126]. Human granulocytic anaplasmosis (HGA), caused by Anaplasma phagocytophilum is most commonly seen in the upper Midwestern states and the Northeastern United States [115]. HGA is typically a less severe disease than HME. It is found in the same geographic areas as babesiosis and Lyme disease and transmitted by Ixodes scapularis and by Ixodes pacificus, the same ticks that transmit Borrelia burgdorferi and Babesia species. Coinfection with A. phagocytophilum, Babesia spp, and B. burgdorferi has been reported [115,127]. Ehrlichia ewingii infection has been reported to cause a granulocytic ehrlichiosis in the Southeastern United States, primarily in immunocompromised hosts [115]. In contrast to most tick-borne illnesses, ehrlichiosis and anaplasmosis are more frequently seen in middle-aged and older individuals [126,127]. Cases most often present in spring and summer, but have been reported in every month of the year [126]. HME may follow a fulminant course in HIV-infected individuals [128]. Leukocyte counts are generally low or normal with a shift to immature forms; elevated transaminases and thrombocytopenia are typically found if patients are followed carefully [125,127]. The diagnosis may be confirmed by the observation of clumps of organisms within leukocytes, termed morulae, but the sensitivity of microscopy in the first week of illness is only 60%, even in very experienced hands [127]. Sensitivity is even lower later in the course. The diagnosis may be confirmed serologically or by a PCR assay at a reference laboratory [115], but therapy may need to be initiated while awaiting results if suspicion is high. The treatment of choice for both HME and HGA is doxycycline; rifampin has been used if doxycycline is contraindicated [127]. Owing to the overlap in clinical syndromes and the uncertainty of diagnosis early in
the course, it is important to be certain that RMSF has been ruled out if an alternative agent to doxycycline is selected.

*Capnocytophaga* spp. are fastidious gram-negative rods that cause soft tissue infections (including gangrene), fever of unknown origin, bacteremia, endovascular infections including endocarditis, and meningitis [129–131]. *C. canimorsus* is normal oral flora in dogs, and infection is often associated with a dog bite. Cases have been reported in association with cat bites and with nontraumatic exposure to the oral secretions of dogs. Several other species of the *Capnocytophaga* genus are normal oral flora of humans, and may cause bacteremia in the setting of cancer chemotherapy [132,133]. Compromised hosts, particularly those with anatomic or functional asplenia or alcoholism, may follow a severe course of illness, especially if bacteremia is complicated by DIC [129].

*Capnocytophaga* spp. are resistant to many antibacterial agents that are commonly used to treat skin and soft tissue infections, including oxacillin and cefazolin. Ampicillin-sulbactam is a good empiric choice for serious soft tissue infection when there is a history of a dog bite. Clindamycin can be used for culture-proven cases of monomicrobial infection with *Capnocytophaga* in the case of penicillin allergy [132], but it is not active against *Pasteurella multocida*, which is a common pathogen in cases of dog or cat bites. Imipenem-cilastin is another alternative active against *Capnocytophaga* and *P. multocida* as well as other common pathogens of skin and soft tissue except MRSA.

Chapter 75

Acute Infection in the Immunocompromised Host

JENNIFER S. DALY • ROBERT W. FINBERG

Advances in the management of neoplastic diseases, transplant immunology, and the therapy of autoimmune diseases have resulted in marked improvements in life expectancy and the quality of patients’ lives. However, patients with autoimmune diseases, neoplasia, or transplantation become highly susceptible to infection by virtue of their associated therapies or by the nature of their underlying illness. Infection has been and remains a leading cause of death among patients with leukemia and lymphoma and a major cause of morbidity and mortality in patients with solid tumors or transplants [1–4]. Rapid progression of fungal, bacterial, and mycobacterial infections occurs in patients given monoclonal antibodies to treat Crohn’s disease and autoimmune diseases such as rheumatoid arthritis [5–7]. The epidemic of human immunodeficiency virus (HIV)-1 infection has added to the numbers of immunocompromised hosts by virtue of the central event of the virus’s pathogenesis: a progressive, irreversible weakening of cell-mediated immunity unless the patient responds to antiretroviral agents (see Chapter 76).

Traditionally, infection has accounted for up to 75% of deaths in patients with acute leukemia or Hodgkin’s disease [1,8] or in transplant recipients [3,9], but with advances in prophylaxis and management, deaths because of infections have decreased to about 50%, whereas death owing to graft versus host disease, relapse of malignancy, and multiorgan failure have increased [10–13]. Once patients require intensive care unit (ICU) care, the mortality increases, and the 1-year survival of cancer patients that require mechanical ventilation in the ICU is below 11% for some centers [14], with acute mortality between 44% and 74% [15–17]. Although intensive efforts are clearly beneficial for stem cell transplantation patients requiring ICU care for the pre-engraftment period, patients with graft versus host disease following engraftment have
the worst prognosis [14]. Early ICU admission has been advocated based on one small study demonstrating that among patients initially thought to be too sick to benefit from ICU care, many were subsequently admitted to the ICU, and did well [18].

Although a great variety of microorganisms have been noted to cause severe, life-threatening infections in immunocompromised hosts, the clinician can formulate a diagnostic plan and decide on empiric therapy by giving careful consideration to the nature, duration, and severity of the immunosuppression that is causing the patient’s predisposition to infection. Infection can arise as a consequence of derangements in host defenses that result from the primary disease, the medical and surgical treatment of the condition, or a combination of these factors. Additionally, immunocompromised patients are likely to manifest their infections in ways that are characteristically different from those of patients with intact immune responses.

**IMMUNE DEFECTS AND ASSOCIATED ORGANISMS AND INFECTIONS**

Underlying disease or treatments affect different aspects of the immune system and, depending on the type of defect, are associated with predisposition to infection with specific classes of organisms or disease syndromes. A level of suspicion of infection with certain organisms depends on the specific immune defect, the duration of immunosuppression, surgical and medical interventions, colonization with nosocomial pathogens, and previous latent or asymptomatic infections that may reactivate after immunosuppression. In general, the most common sites of serious, definable infection in the immunocompromised host are the bloodstream (including infection related to intravenous [IV] access devices), lung, and mucocutaneous surfaces (including oral, gastrointestinal, skin, and perirectal areas). The diverse organisms frequently or uniquely associated with infections in the compromised host are listed in Table 75.1. As a general rule, patients whose underlying disease or treatment leads to a lack of T cells or any abnormality in T cell–macrophage activation will be subject to infections with organisms that live intracellularly such as viruses, fungi, and intracellular bacteria (e.g., *Listeria, Legionella, mycobacteria*). Patients with profound neutropenia will be subject to infection with aerobic Gram-positive and Gram-negative bacteria that live on the skin and within the gut. Patients lacking antibodies or a spleen will be unusually susceptible to infection with encapsulated bacteria (*Streptococcus pneumoniae, Haemophilus influenzae, and Neisseria meningitidis*). As
for any patient in the ICU, the immunocompromised patient is susceptible to infection with bacteria that are found in ventilators or spread in the ICU. The most common organisms found in patients with bloodstream infections vary by center and whether or not patients are on prophylactic antimicrobials \[19\]. *Escherichia coli* and *Staphylococcus aureus*, including methicillin-resistant *S. aureus* (MRSA), continue to be common, followed by coagulase-negative staphylococci, enterococci including vancomycin-resistant enterococci, *Pseudomonas aeruginosa*, *Klebsiella* species, *Enterobacter* species, and various streptococci \[20–23\]. In patients with neutropenia and documented bacteremia, Gram-positive organisms predominate over Gram-negative bacilli in most centers, and the presence of an intravascular device is associated with having a positive blood culture \[24\], although some centers have noted an increase in patients with bacteremia because of multiply resistant Gram-negative bacilli \[25\]. Fungal infections increase in frequency with increasing duration of the immunocompromised state and therapy with broad-spectrum antibiotics and choice of antifungal prophylaxis.

### Anatomic Barriers

The skin and mucosal surfaces serve a primary role in the defense of the host against invasion by endogenous and exogenous microorganisms. Mucous membrane ulceration in the mouth and gastrointestinal tract can occur spontaneously in patients with acute leukemia, although this complication more commonly arises after chemotherapy. In patients with solid tumors, disruption of mucocutaneous barriers can result from invasion, obstruction, or perforation by the malignancy. Iatrogenic disruption of the normal skin and mucosal barriers results from medical and surgical support interventions common to the ICU, including intravascular and urinary catheters [26] (see Chapter 79 on catheter infections). Organisms that most frequently cause infection of intravascular catheters include coagulase-negative staphylococci, S. aureus, enterococci, Corynebacterium species (including C. jeikeium), and Candida species [1,26,27]. Percutaneously inserted central catheters are associated with an increased risk of both infection and thrombosis.
The risk of these infections can be reduced, although not eliminated, through the use of permanent, subcutaneously tunneled catheters (e.g., Hickman, Broviac, Groshung, or Portacath systems) [29]. Genitourinary tract infections are associated with disruption of the urinary tract integrity, as occurs with urinary catheter drainage, pelvic tumors, or radiation with resultant ureteral obstruction, or after renal transplant.

The gastrointestinal tract is a source of occult bacteremia or fungemia, because chemotherapy and neutropenia cause breakdown in normal mucosal defenses of the gut, facilitating entry of bacteria or yeast into the bloodstream. Clinically apparent intestinal problems seen in neutropenic patients include typhlitis, anorectal cellulitis/fasciitis/abscess, necrotizing colitis, and *Clostridium difficile*–associated colitis caused by chemotherapy or antibiotics [30]. Typhlitis, an inflammatory disease of the cecum, may lead to toxic megacolon and perforation and requires a high index of suspicion, and prompt diagnosis. Unusually severe and prolonged viral gastroenteritis caused by cytomegalovirus, adenovirus, rotavirus, and Coxsackie virus has been observed in marrow transplant recipients [31–33]. Herpes simplex virus (HSV) should be suspected as a possible cause for any lesion of mucous membranes of an immunocompromised host, and may also cause fatal hepatitis [34]. Adenovirus may cause hepatitis, pneumonitis, or hemorrhagic cystitis [33], and BK and JC viruses may cause persistent fever and renal insufficiency [35,36]. Necrotizing gingivostomatitis caused by oral anaerobes as well as severe periodontal infection may also complicate neutropenia.

**Defective Phagocytosis**

Neutrophils and macrophages provide defense against infection by bacteria and many fungi. Patients with leukemia, particularly an acute type of leukemia, commonly have a reduction in their absolute number of circulating neutrophils; qualitative defects of neutrophil function have also been described in these patients. Aplastic anemia, as well as extensive bone marrow involvement caused by lymphoma or metastatic solid tumors, may result in neutropenia. By far the most common cause of neutropenia, however, is cytotoxic chemotherapy. Patients whose neutrophils are reduced in number by malignancy or chemotherapy are at risk for the development of spontaneous bacteremia. The risk becomes significant at absolute neutrophil counts that are persistently below 500
per μL (or below 1,000 per μL and falling) and increases dramatically at counts below 100 per μL [33,37].

Invasive and disseminated fungal infections also may be a consequence of neutropenia and become more common after the neutropenic patient has received broad-spectrum antibiotic therapy [33,38]. Candida and Aspergillus species are the most common fungal pathogens observed in neutropenic hosts, but unusual genera such as Fusarium, Trichosporon, Scedosporium (Pseudallescheria), mucormycoses, and Cunninghamamella have been described with increasing frequency [39–41].

Altered Humoral Immunity

B-cell lymphocytic function and antibody production may be impaired in untreated patients with chronic lymphocytic leukemia, multiple myeloma, and lymphoma. Acquired deficits in antibody production may also be encountered in otherwise healthy patients (e.g., immunoglobulin A deficiency, common variable immunodeficiency). Hypogammaglobulinemia or impaired antibody response predisposes patients to infections attributable to encapsulated bacteria such as S. pneumoniae, H. influenzae, and N. meningitidis; moreover, these infections are likely to be sudden, severe, and associated with fulminant bacteremia [33]. Infections caused by enteric Gram-negative bacilli and P. aeruginosa also may be seen in previously untreated patients with defective humoral immunity secondary to B-cell malignancies.

Impaired Cell-Mediated Immunity

T cell–mediated immunity includes cytotoxic (killer) T cells, activated macrophages, and antibody-dependent cellular cytotoxicity. These critical components of immunity are impaired in patients with Hodgkin’s disease [42] and other lymphomas and in those taking antirejection drugs (e.g., cyclosporine, mycophenolate mofetil, tacrolimus, sirolimus, and antilymphocyte antibodies), antibodies against tumor necrosis factor (TNF)-α, or corticosteroids [3,6,7,43]. Patients infected with HIV-1 experience a progressive and devastating loss of T cell–mediated immunity. This virus selectively infects and lyses CD4+ lymphocytes that play a central role in governing humoral and cellular immune responses. Defects in cell-mediated immunity are commonly associated with primary or reactivation of infection by herpes viruses (varicella-zoster virus, cytomegalovirus, HSV), protozoa (Toxoplasma gondii and Cryptosporidium species), fungi (Pneumocystis jiroveci, Cryptococcus neoformans, Histoplasma capsulatum, Coccidioides immitis, and Candida species), helminths (Strongyloides stercoralis), mycobacteria (M. tuberculosis, M. avium-intracellulare, M. kansasii, M. chelonae),
and other intracellular bacteria (Listeria monocytogenes, Salmonella, and Legionella species) [3,42,44].

Immunosuppressive Medications

Cytotoxic chemotherapy, corticosteroids, anticytokine antibodies, and other immunosuppressive therapeutic regimens can alter host defenses in several ways. Immunosuppressive effects depend on the class of drug, dose and duration of therapy, and timing relative to other therapeutic modalities (e.g., radiation, which may contribute to neutropenia). Several new inhibitors of cytokines and cytokine activation (including anti-TNF and anti-IL-1 antibodies) used to treat autoimmune disorders have resulted in the reactivation of latent tuberculosis and histoplasmosis as well as invasive aspergillosis [6,45,46]. Physicians need to be aware of the fact that patients on such agents have a risk of reactivation of intracellular organisms [47].

Antimicrobial Therapy

Antibiotic therapy is highly effective in the management of documented infections and febrile episodes in the compromised host. These agents are double-edged swords, however, and promote a shift toward increasing frequency of infections caused by progressively more resistant organisms, including P. aeruginosa, Enterobacter species, extended spectrum β-lactamase–producing Klebsiella species, multiply resistant enterococci, MRSA, and fluconazole-resistant Candida species. Unusual, intrinsically resistant bacteria (e.g., Capnocytophaga and Corynebacterium species) and fungi (e.g., Scedosporium and Fusarium species) are being seen with increasing frequency in oncology centers.

Splenectomy

Splenectomy, which results in the loss of the reticuloendothelial capacity to clear organisms from the bloodstream, predisposes patients to fulminant, overwhelming bacteremia caused by encapsulated bacteria (S. pneumoniae, H. influenzae, and N. meningitidis) as well as S. aureus. Although the syndrome of overwhelming postsplenectomy infection is most common among patients whose splenectomy was for malignancy or reticuloendothelial disease, overwhelming postsplenectomy infection can occur in any splenectomized patient regardless of underlying disease or interval since surgery (see Chapter 74). Accordingly, fever higher than 38°C in the splenectomized patient warrants immediate investigation and empiric therapy for possible bacteremia or focal bacterial infection. Consideration of ICU admission and presumptive antibiotic therapy is appropriate if the patient appears systemically toxic. A third-generation
cephalosporin (e.g., ceftriaxone or cefotaxime) is reasonable empiric therapy, although if skin or skin structure infection is present, vancomycin should be added because of the increasing likelihood of community-acquired MRSA.
DIAGNOSTIC APPROACH TO FEVER

In the evaluation of acutely ill, immunocompromised patients with fever in the ICU, a meticulous and thorough history and physical examination must be performed initially and repeated daily. Particular attention should be directed to sites of high risk, such as the oropharynx, anorectal region, lungs, skin, optic fundi, and vascular catheter sites. Patients with focal abnormalities such as solid tumors, organ transplantation, or recent surgery need to have these specific sites investigated with special care. Patients with neutropenia and infection exhibit fewer and less striking physical findings of infection (e.g., local warmth, swelling, adenopathy, exudate, or fluctuance) than are ordinarily encountered in immunocompetent individuals (see Chapter 71).

Initial laboratory studies that should be performed in the evaluation of the acutely ill, febrile, compromised host include (a) cultures of blood, (b) cultures of urine if symptoms or abnormal urinalysis, (c) routine sputum culture, if the patient has symptoms or signs of pulmonary disease, (d) swab, aspiration, or biopsy of suspect skin, mucous membrane, or other lesions for smears, cultures, and pathologic examination, (e) semiquantitative culture of IV catheters in place when fever develops; if possible (if the cannula is a critical lifeline or a subcutaneously tunneled device that shows no local signs of infection, removal can be deferred pending results of routine blood cultures), (f) chest radiography, and (g) serum chemistries (i.e., electrolytes, liver chemistries, creatinine), in part to detect possible visceral involvement or multiorgan failure caused by disseminated infection and also to serve as baselines for monitoring possible adverse reactions to subsequent antimicrobial therapy.

Patients with defects of cell-mediated immunity (e.g., HIV-1 infection, lymphoma, transplant recipients) often harbor organisms that are best diagnosed by histologic examination (e.g., Pneumocystis jiroveci, T. gondii) or special culture techniques (e.g., mycobacteria, viruses). In instances in which such organisms are high in the differential diagnosis, initial evaluation often entails immediate biopsy of the pathologic process. Localizing symptoms and signs may indicate the need for other studies, such as computed tomography (CT), magnetic resonance imaging (MRI), or nuclear medicine scans (e.g., gallium-67 scan to detect P. jiroveci pneumonia [PCP]). Tachypnea warrants arterial blood gas studies because progressive hypoxemia in the absence of radiographic findings can be an early indicator of pulmonary infection, especially PCP, and may indicate a need for bronchoscopy. Depending on the nature of the abnormality and the state of immunosuppression, consider lung biopsy and/or quantitative culture of washings or protected brushings.
obtained through the bronchoscope if patient presents with pulmonary symptoms and a new finding on chest X-ray [48,49].
APPRAOCH TO SPECIFIC INFECTIOUS DISEASE PRESENTATIONS

Acute Fever Without Obvious Source: Neutropenia

In patients with fever and neutropenia, shock may be an early complication of bacteremia. Although now that antibiotic prophylaxis during episodes of neutropenia is widely used, only 20% to 30% of febrile neutropenic patients have documented infection [50,51]; multiple randomized trials and consensus guidelines support the initiation of empiric broad-spectrum antibiotic therapy for all patients with fever greater than 38°C and absolute neutrophil counts less than 500 per μL (or less than 1,000 per μL and falling) [37,38,52,53]. The immediate institution of such therapy in these patients (even in the absence of documentation of bacterial infection) dramatically reduces morbidity and mortality. The most rapidly fatal infectious agents that are documented to cause acute fever in the critically ill neutropenic cancer patient are enteric Gram-negative bacilli (e.g., *E. coli*, *Klebsiella* species, *Proteus* species), *P. aeruginosa*, and *S. aureus* [37,38]. In the patient without an obvious site of infection, initial empiric antibiotic therapy should be directed against these pathogens (Table 75.2). Such therapy should take into consideration idiosyncrasies of the antimicrobial susceptibility patterns of organisms in the institutions where the patient has resided in the months before infection and recent antibiotic use in a particular patient.

\[a\]The choice of regimen should be based on local resistance patterns and the individual patient’s most recent prior antimicrobial therapy.

Despite the testing of hundreds of antibacterial regimens for use in patients with fever and neutropenia, there is no consensus on one best regimen. For patients who have not received prior antibiotic prophylaxis or therapy, a single antipseudomonal third-generation cephalosporin (e.g., ceftazidime), piperacillin/tazobactam, or a carbapenem (imipenem, or meropenem) constitutes an appropriate regimen [54–56]. Although the use of piperacillin/tazobactam alone or cefepime is somewhat controversial, none of the \(\beta\)-lactam agents above are clearly preferred except as dictated by local resistance patterns or cost [52,54,56]. Another review provides the evidence from meta-analyses that empiric use of aminoglycosides with broad-spectrum \(\beta\)-lactam agents is not needed [55] (Table 75.4).

### TABLE 75.4 Advances in Management Based upon Randomized Controlled Clinical Trials and Meta-Analyses of These Trials

**Acute fever without obvious source: Neutropenia**
- Broad-spectrum antibiotic therapy should be started for all immunocompromised patients with fever greater than 38°C and absolute neutrophil counts less than 500 per mm\(^3\) (or less than 1,000 per mm\(^3\) and falling) [37,38,52,53]
- There is no benefit to continuing vancomycin after 72 h unless a Gram-positive infection is documented [60–62,76,114–116]
- There is no benefit to adding an aminoglycoside to a \(\beta\)-lactam agent in patients with fever and neutropenia [55]

**Persistent fever or recurrent fever with obvious source: Neutropenia**
- Empiric antifungal with an amphotericin B preparation, voriconazole, or caspofungin should be started for the immunocompromised patient with
neutropenia and fever of 4–7 d duration [60–62,114,115,117]

Treatment of aspergillosis

- Voriconazole is the drug of choice for documented infections because of Aspergillus [79]

Prophylaxis of fungal infections

- In patients undergoing chemotherapy for acute myelogenous leukemia or myelodysplastic syndrome, posaconazole prevented invasive fungal infections more effectively than did either fluconazole or itraconazole and improved overall survival. There were more serious adverse events possibly or probably related to treatment in the posaconazole group [110,118]
- Both fluconazole and itraconazole have shown benefit for prophylaxis in patients after allogeneic stem cell transplant [119]

For a patient in septic shock who is admitted to the ICU or in institutions with endemic resistant Gram-negative bacteria, a multidrug regimen may be indicated. For patients with immediate hypersensitivity reactions to cephalosporins and penicillins, aztreonam has activity against Gram-negative bacilli and can be used with an antimicrobial agent with activity against a broad spectrum of Gram-positive organisms (e.g., vancomycin is added to this regimen because aztreonam has no Gram-positive activity). Because of the increased prevalence of methicillin-resistant staphylococci, recent guidelines have recommended routine initial inclusion of vancomycin in empiric regimens for patients in shock, particularly in patients on antimicrobial prophylaxis and those with evidence of skin or skin structure infections or with inflammation at the site of or dysfunction of indwelling plastic venous access catheters [52]. Randomized controlled trials have demonstrated no benefit to continuing vancomycin after 72 hours unless patients demonstrated a Gram-positive infection [52,57].

Most standard regimens are designed for patients who have not previously received antibiotics. The development of fever with systemic symptoms such as shock or respiratory distress in a patient on antibiotic therapy requires a change in therapy to include organisms that are known to be resistant to classes of antibacterials the patient has received. For example, in a patient who recently has received cephalosporins, the choice of piperacillin/tazobactam or imipenem may be preferable to ceftazidime especially if expanded spectrum β-lactamase–producing organisms are established flora in the local ICU.

After initial evaluation of the patient and initiation of empiric antibiotic therapy, subsequent management is based on (a) identification of a focus of infection, (b) isolation of an etiologic agent, (c) defervescence versus continued fever, and (d) duration of neutropenia. In the patient for whom
an infection has been documented clinically or by culture, antibiotics should be continued as appropriate for the site of infection, susceptibility profile of pathogens, and the patient’s clinical response. Even when a specific pathogen is identified by culture, in patients who are neutropenic, a broad-spectrum regimen usually is maintained for the duration of neutropenia [38,52,58]. For patients likely to have permanent or extremely prolonged granulocytopenia, attempts to stop therapy are reasonable but should be made with continuing close clinical observation [52,59].

If fever has not been eliminated or the patient continues to have evidence of ongoing sepsis, the search should continue for potential sites of focal infection (skin, optic fundi, oropharynx, chest, abdomen, and perirectal area). The serial, empiric addition of one antibiotic after another without culture data is not efficacious in most settings and may lead to confusion in the event that an adverse reaction occurs [52]. Cephalosporins and vancomycin can cause bone marrow suppression and lead to colonization with resistant organisms. The addition or sequential substitution of multiple cephalosporins may induce β-lactamase production by some organisms.

**Persistent or Recurrent Fever Without Obvious Source: Neutropenia**

Should fevers persist for 4 to 7 days of neutropenia, randomized controlled trials have found that empiric antifungal therapy with an amphotericin B preparation, voriconazole, or an echinocandin [60–62] is appropriate. The rationale for such therapy is that it is difficult to culture fungi before they cause disseminated disease and that the mortality from disseminated fungal disease among neutropenic hosts is high. *Candida* and *Aspergillus* species are common pathogens, and *Fusarium, Trichosporon*, and *Bipolaris* species are seen occasionally but are becoming more common [63–66]. The use of the serum assay for galactomannan as a marker for aspergillus infection is controversial because sensitivity is low and there may be false-positive results in patients receiving piperacillin [67,68]. Another serum assay that tests for 1,3 β-D-glucan antigenemia shows promise, but serial monitoring is needed and predictive value for invasive fungal infections varies in different centers [69,70]. More research is needed on both of these assays.

Patients at particularly high risk of disseminated fungal disease include those with (a) prolonged granulocytopenia, (b) parenteral nutrition, (c) *Candida* colonization in oropharynx or urine, (d) corticosteroid therapy, and (e) advancing multiple organ dysfunction (renal, hepatic, pulmonary). Moreover, multiorgan failure often is a reflection of
disseminated candidiasis [71]. The use of antifungal prophylaxis with the imidazoles (fluconazole) has caused a shift in the species of Candida-causing infection from C. albicans and C. tropicalis to the more imidazole-resistant C. krusei and C. glabrata [72], and with the use of posaconazole or voriconazole, a shift has started to occur to more infections because of Zygomycetes [73,74]. Hepatosplenic (also called chronic disseminated) candidiasis presents with fevers and elevation of serum alkaline phosphatase that continue through the return of neutrophils to greater than 1,000 cells per mm$^3$ [75]. Multiple embolic lesions are present in liver and spleen, and prolonged therapy with amphotericin B, itraconazole, fluconazole, or an echinocandin depending on the susceptibility of the organism, is beneficial [76]. Use of biomarkers and direct testing are controversial and not uniformly available [77,78].

Based on the findings from a randomized clinical trial of primary therapy and randomized studies of salvage therapy, voriconazole is the drug of choice for infections caused by Aspergillus [79,80]. However, an amphotericin preparation continues to be the drug of choice when a fungal infection is suspected in patients already receiving an azole antifungal [74]. Amphotericin has activity against Aspergillus, the zygomycetes, and many other filamentous fungi. According to data from randomized clinical trials, the newer preparations of amphotericin B appear to decrease renal toxicity while maintaining efficacy: therefore, amphotericin B complexed with cholesteryl sulfate, with liposomal vesicles, or with a bilayered lipid membrane has become standard for use in patients on other nephrotoxic drugs or those with impaired renal function, despite their higher cost [81] (see Chapter 73). Prognosis remains poor, however, for patients treated for documented invasive fungal infection in the setting of persistent neutropenia [63,82]. Most ICU patients who remain febrile and neutropenic after 4 to 7 days of broad-spectrum antibacterials should be treated with voriconazole, an amphotericin B preparation or an echinocandin, although in selected low-risk patients (where the risk of Aspergillus or Zygomycetes is low), itraconazole or fluconazole is equally efficacious as shown in open randomized clinical trials and endorsed in expert reviews of these studies [62,83–86].

**Pneumonia in the Compromised Host**

The lung is one of the most common identifiable sites of infection in immunocompromised patients [2,48,87]. Pulmonary disease can be caused by a wide variety of agents, including bacteria, protozoa,
helminths, viruses, fungi, and mycobacteria (Table 75.3) (see Chapter 181). The differential diagnosis is made even more difficult by the various noninfectious pulmonary complications that can present abruptly with acute respiratory symptoms and fever. These include underlying malignancy or vasculitis, drug toxicity, interstitial fibrosis, diffuse alveolar hemorrhage, radiation pneumonitis, cardiogenic pulmonary edema, bronchiolitis obliterans organizing pneumonia, pulmonary alveolar proteinosis, and pulmonary embolism [48,87].

Radiation

Pneumonia in the immunocompromised patient often presents without the symptoms and signs seen in normal hosts. Regardless of cause, fever and progressive shortness of breath (and concomitant tachypnea and arterial hypoxemia) tend to be common symptoms; in the neutropenic patient, cough, sputum production, and physical examination (as well as radiographic) findings are likely to be unimpressive or absent. Chest radiographs should be obtained promptly in the compromised patient with fever or dyspnea. High-resolution CT or MRIs will often reveal infiltrates or masses that cannot be appreciated on conventional X-rays and thus are recommended in cases in which there is question about the diagnosis [88].

Differential Diagnosis

Developing an appropriate differential diagnosis for the causative agents of pneumonia in the immunocompromised host rests first on an appreciation of the nature, severity, and duration of the immune suppression. In addition to being susceptible to conventional respiratory tract pathogens (S. pneumoniae, H. influenzae) hospitalized immunocompromised hosts are prone to Gram-negative bacillary pneumonia; those with prolonged (greater than 7 days) or profound (less than 100 neutrophils per μL) neutropenia may become infected with
Aspergillus or Zygomycetes spp [2]. T-cell–deficient hosts (e.g., patients with HIV infection, transplant, or lymphoma) are more likely to acquire PCP [89] or infection with CMV, HSV [90–92], endemic fungi (Cryptococcus, Histoplasma) [46,93,94], Nocardia spp, or intracellular bacteria (mycobacteria, Legionella spp) [95–97]. Patients who have resided in tropical countries may reactivate latent infection by Strongyloides stercoralis in the setting of altered cell-mediated immunity. Pulmonary infiltrates, polymicrobial bacteremia, and bacterial meningitis are the hallmarks of this syndrome [98]. Patients with deficient neutrophil and T-cell function (e.g., bone marrow transplant recipients) may be at risk for all of these pathogens.

Chest radiographs may provide useful clues; focal or multifocal infiltrates tend to suggest infections by bacteria or fungi, but are unlikely to provide a definitive diagnosis. CT scanning often provides more information, including the detection of lesions not seen on routine chest radiograph [48]. Diffuse disease is more characteristic of viral causes (HSV, CMV), PCP, or noninfectious processes (drug toxicity, lymphangitic carcinomatosis, and radiation pneumonitis). Cavitary disease can be seen with some of the necrotizing Gram-negative bacilli such as P. aeruginosa as well as S. aureus and anaerobes (e.g., postaspiration or postobstructive). Cavities also can be a late finding with pneumonia because of Aspergillus, Zygomycetes, and Nocardia spp. It is impossible, however, to make firm rules with regard to radiographic patterns. Gram-negative bacilli or Legionella may progress to diffuse disease or incite the acute respiratory distress syndrome. Patients with severe defects in cell-mediated immunity may manifest a miliary pattern caused by disseminated tuberculosis or histoplasmosis. Conversely, radiation pneumonitis may present as focal, sharply demarcated infiltrates confined to the irradiated portion of the lung.

**Diagnostic Approach and Empiric Therapy**

The diagnostic approach to pulmonary disease in the immunocompromised host also depends on the nature of the immune deficit. As a general rule, all accessible sites (blood, urine, and sputum) should be cultured, although sputum of high quality is obtained rarely in these circumstances. In neutropenic hosts, empiric antibacterial therapy is begun at the outset regardless of radiographic pattern, using one of the regimens discussed previously for fever and neutropenia [37,38]. In the case of ventilated inpatients, treatment of pneumonia must include antibiotic(s) that are effective against organisms that are likely to be present in the ICU (some of these organisms are resistant to antibiotics typically used in treating febrile, neutropenic patients). These regimens typically contain more than one antibiotic and they should be adjusted...
based on the cumulative susceptibility report of the hospital or unit. Although logical, the use of “protected specimen brushes” has not been shown to be of clear clinical value and should not be a reason to perform an invasive procedure in an immunocompromised patient [99].

If a clinical response occurs in a neutropenic patient, therapy is continued until neutropenia resolves. In the setting of persistent neutropenia, a clinical picture of progressive pulmonary disease despite antibiotic therapy suggests invasive disease caused by fungi found in the environment (a variety of “saprophytic” fungi are a major concern: especially *Aspergillus*, but also *Rhizopus, Fusarium*, and *Trichosporon* spp) [39,65,66]. Expectorated sputum, bronchial brush specimen cultures, or bronchial lavage fluid may provide presumptive evidence of these pathogens, but prompt definitive diagnosis often requires open or thoracoscopically guided lung biopsy. Transbronchial biopsy is often nondiagnostic. Typically, pneumonia caused by *Aspergillus* or *Zygomycetes* spp causes areas of lung infarction that may be missed by transbronchial biopsy [100,101]. CT scans may show the classic “crescent” sign in patients with aspergillosis, but this is a sign of late disease, and although it may be helpful diagnostically in patients who are recovering, early diagnosis is important to prevent mortality in persistently neutropenic patients. Unlike bacteria, which are usually easy to culture, fungi are often not isolated from cases where histopathology eventually demonstrates their presence. Although PCR-based techniques have yet to be of demonstrated clinical usefulness in these clinical situations, measurements of polysaccharide antigen in serum or other body fluids have been of demonstrated utility for the diagnosis of both *Cryptococcus*- and *Histoplasma*-associated pneumonia.

The standard approach to therapy of confirmed pulmonary disease caused by *Aspergillus* is to treat with voriconazole because this agent has been shown to be superior to treatment with amphotericin B preparations [80,102]. Although the use of combinations of antifungal agents (including echinocandins and azoles as well as echinocandins and amphotericin) has rationale, support from animal data, and anecdotal human experience, large trials have yet to be performed, making it difficult to recommend this approach at this time unless single agents have failed. There is no established therapy for some emerging fungal pathogens such as *Trichosporon* or *Fusarium* spp, although encouraging results have been reported in a few cases using posaconazole, voriconazole, or isavuconazole [102,103].

For patients with compromised T-cell immunity, the list of diagnostic
possibilities is longer and more diverse, making a single formula for empiric therapy a virtual impossibility. Clinicians caring for these patients should be guided by both the type of the underlying immunodeficiency and the patient’s previous experiences with both pathogens and antimicrobial agents. Expectorated or induced sputum may demonstrate the organism by special stains in a minority of cases (P. jiroveci, M. tuberculosis, Nocardia asteroides), but flexible bronchoscopy with lavage or transbronchial biopsy and open or thoracoscopically assisted lung biopsy may be required in order to make a diagnosis for these patients [48,104,105] (see Chapter 10). Bronchoscopy is particularly helpful for diffuse or interstitial disease, in which it provides not only lavage fluid with reasonable diagnostic accuracy for infectious agents such as P. jiroveci and bacteria but pathologic specimens that may allow diagnosis of CMV infection, drug pneumonitis, hemorrhage, or lymphangitic carcinomatosis. In patients with focal or nodular disease, thoracoscopically assisted biopsy is likely to yield the best results.

For the immunocompromised host (non–HIV infected), the diagnosis of PCP often requires bronchoscopy with bronchoalveolar lavage with or without biopsy. A variety of other infections also require biopsy for diagnosis. It is reasonable to treat (empirically) with trimethoprim–sulfamethoxazole (15 per kg of the trimethoprim component IV daily divided every 6 or 8 hours) while arrangements are made for diagnostic procedures, because the organisms persist for the first few days of treatment. It is usually an error to postpone performing bronchoscopy (with biopsy) or thoracoscopically guided lung biopsy for severely ill immunocompromised patients with pulmonary infiltrates in the hope that they will improve, because clinical deterioration may make the procedure (and the diagnosis) impossible. If PCP is confirmed and the patient has severe renal insufficiency, serum drug concentration monitoring, if available, should be used to adjust therapy to obtain a peak serum sulfamethoxazole level of 100 µg per mL or trimethoprim levels of 5 to 8 mg per µL [106]. An alternative diagnosis, established by histologic or microbiologic techniques, allows institution of specific therapy, such as acyclovir for HSV pneumonia; ganciclovir for CMV pneumonia; trimethoprim–sulfamethoxazole for nocardiosis; or corticosteroids for radiation pneumonitis, bronchiolitis obliterans with organizing pneumonia, acute fibrinous and organizing pneumonia, or drug-induced disease [48,104,107,108].
PREVENTION OF INFECTION

Increasing emphasis is being placed on the prevention of opportunistic infections in immunocompromised hosts. These strategies have taken many different forms. Early efforts were directed at modifications of the environment of neutropenic patients through laminar airflow, nonabsorbable antibiotics, and elaborate efforts at disinfecting the inanimate environment. These approaches have proven expensive and laborious, and because they did not affect either disease remission or mortality, they have been abandoned by most centers.

Oral fluoroquinolone (and trimethoprim–sulfamethoxazole) administration has been studied in patients with prolonged neutropenia. These agents reduce levels of aerobic Gram-negative bacilli in the gut lumen, the major reservoir for dissemination of infection in the neutropenic host, and studies document the efficacy of levofloxacin for preventing infections and hospitalizations in patients with chemotherapy-induced neutropenia [109].

Antifungal prophylaxis with oral fluconazole (400 mg orally daily or 200 mg IV every 12 hours) has proved effective in reducing infection by Candida spp in bone marrow transplant recipients [81] (see Chapter 64). Recent studies suggest that posaconazole, which has a much broader spectrum than fluconazole (including aspergillus), is efficacious in preventing fungal infections in severely neutropenic patients, hematopoietic stem cell transplant patients, and those with graft versus host disease [110].

Antiviral prophylaxis with acyclovir has been shown to reduce mucositis and mucocutaneous infections by HSV in transplant recipients and in patients with leukemia [111,112]. Although prophylactic administration of ganciclovir has been demonstrated to decrease CMV disease in solid organ transplant recipients, the administration of this agent to bone marrow transplant patients resulted in neutropenia. Consequently, most centers are now using “preemptive” treatment with ganciclovir (beginning treatment only when DNA levels are increased in the serum of patients at risk) (see Chapters 63 and 64).

Administration of granulocyte–colony stimulating factors hastens bone marrow recovery and shortens the duration of neutropenia in some patients receiving chemotherapy. Consensus guidelines suggest that they should be used to support dose-intense chemotherapy and have little
impact on mortality in patients with existing neutropenia and fever and should not be used as a routine adjunct to antimicrobials [113].

6. Singh N: Trends in the epidemiology of opportunistic fungal

2014.

At the start of the pandemic in the 1980s, AIDS was considered to be rapidly fatal in almost all cases, and the benefits of aggressive interventions, including treatment in the intensive care unit (ICU), were questioned for patients with advanced disease. Respiratory failure because of *Pneumocystis jirovecii* pneumonia (PCP) was by far the most common disorder that prompted ICU admission, outcomes were uniformly dismal, and ICU admission was often discouraged by clinicians and declined by patients. HIV-infected persons who now have access to effective combination antiretroviral therapy (ART) enjoy much better outcomes. The use of these drugs became the standard of care in 1996, and as a result U.S. mortality rates declined dramatically. For people with HIV infection, mortality reached a peak of around 50,000 per year in 1995, and declined rapidly in the era of effective ART. More recently, death rates have shown a more gradual decline, and were estimated at around 14,000 in 2012 [1]. The improved prognosis in the United States and the developed nations is hampered by limitations to diagnosis and care. In 2011, it was estimated that roughly 25% of HIV-infected individuals in the United States were on treatment with ART and have an undetectable viral load. In this analysis, upward of 20% of people with HIV infection in the United States were undiagnosed [2]. Moreover, improvements of care and survival observed among developed nations still stand in sharp contrast to the global epidemic. In 2014 an estimated 2.0 million people acquired HIV infection, and 1.2 million died [3]. Despite these grim statistics, dramatically scaled-up access to combination ART is now reducing HIV-related mortality and HIV transmission worldwide. Worldwide, an estimated 15 million of the 36.9 million people living with HIV had access to ART as of March 2015 [3].
With the use of effective ART, the spectrum of critical illness related to HIV infection is changing, along with the short- and long-term prognosis for these illnesses. Increasingly, infected individuals who are receiving effective ART have critical illnesses more related to their age than their HIV infection. For some illness such as cardiovascular disease, the risk may be elevated by HIV or its treatment [4]. The use of antiretrovirals entails risk of drug interactions and toxicity, requiring vigilance in the multidrug complexity of ICU care.

**REASONS FOR INTENSIVE CARE UNIT ADMISSION**

The literature on the frequency and reasons for ICU admission in patients with HIV infection must be interpreted with the understanding that with rare exception, each study reviews the experience of a single center and reflects local ICU admission criteria and practice patterns. Care of patients with HIV infection and with critical illness in general may vary widely, so the conclusions from these reports cannot be generalized [5]. The decision on whether to admit HIV-infected patients to the ICU or withhold such treatment varies by hospital characteristics (county/state, Veterans Affairs Medical Centers, church affiliated, voluntary, and for profit) and geographic location, and these differences are maintained after controlling for severity of illness and patient demographic and socioeconomic characteristics. Thus, data on diseases and outcomes from one center cannot be applied reliably to others. Endemic fungi and other pathogens influence ICU admission rates for different diseases; this is important in the United States, where regional differences in HIV/AIDS incidence and prevalence are notable, and may shift over time [1].

Nevertheless, there is evidence that the reasons for ICU admission have changed over the last three decades of the AIDS epidemic, largely because of reduced incidence of opportunistic infections owing to ART. In the era before ART, an estimated 5% to 10% of hospitalizations of patients with HIV infection involved an ICU admission; most patients were admitted for respiratory failure, and PCP was the most common diagnosis [6–8]. Although PCP has always been the most common cause of respiratory failure in patients with HIV infection, it appears that ICU admissions for PCP, and for respiratory failure in general, continue to decline [9,10]. The few studies of intensive care in the era of ART suggest that overall ICU utilization by HIV-infected persons has not declined; respiratory failure is still the most common reason for admission, but its relative frequency is declining as other organ failures are increasing [10]. Patients are also less likely to be admitted for PCP and other HIV-associated opportunistic
infections, and are now more likely to have life-threatening bacterial pneumonia, sepsis, neurologic disorders, and complications of end-stage liver disease [9–14]. Patients may also become critically ill from the toxic effects of antiretroviral medications, or drug interactions, or from an accelerated inflammatory response related to immune reconstitution resulting from the use of ART [15–17].
PULMONARY DISORDERS

Pneumocystis Pneumonia

Pneumonia caused by *Pneumocystis jirovecii* (formerly classified as *Pneumocystis carinii* f. sp. *hominis*) has always been a major cause of illness and death in patients with HIV infection. Once thought to be a parasite, genomic analysis revealed that *P. jirovecii* is in fact a fungus that is species specific and infects only humans [18]. Although the taxonomy of this pathogen has changed, the term PCP is still acceptable shorthand for *Pneumocystis* pneumonia.

Despite immune restoration from ART and effective specific chemoprophylaxis for PCP, this infection still occurs for several reasons: many patients do not know that they have HIV infection until disease advances to a stage where they develop an opportunistic infection; others know that they have HIV but are not receiving medical care; and still others are in care but are either not prescribed or choose not to take prophylaxis or ART [2,19]. Although newer combinations of ART are coformulated and less likely to cause adverse effects, suboptimal adherence leads to selection of HIV mutations that confer drug resistance, and adherence to complex “salvage” regimens with difficult-to-tolerate side effects is often problematic. Some patients take prophylaxis for PCP, but are still so profoundly immunocompromised that it is ineffective [20]. Nevertheless, the incidence of PCP has declined in the era of ART [21].

PCP should be suspected for a patient with known or suspected HIV infection, fever, and progressive cough and dyspnea. Radiographically, the diagnosis is strongly suggested by perihilar or diffuse ground glass opacities, but this pattern is not specific for PCP. Other radiographic findings include pneumatoceles, pneumothorax, nodules, lobar consolidation, and normal images [22]. The diagnosis can be confirmed only by identifying the organism in specimens obtained from the respiratory tract, either in sputum induced by inhalation of hypertonic saline or by bronchoscopy. Although establishing a diagnosis is not difficult, many clinicians treat patients with suspected PCP empirically, reserving bronchoscopy for patients who do not respond to treatment. A decision-analysis model and a retrospective study comparing these two strategies suggest that the outcomes are similar, but no clinical trial has ever evaluated whether initial empiric therapy or a more aggressive diagnostic strategy that includes bronchoscopy is preferable [23,24]. Among intubated patients, the diagnosis may be established easily with bronchoalveolar lavage. A test that has gained acceptance as an indicator
of PCP is the plasma β-D-glucan (BDG) assay. When high values are observed in the context of typical radiographic findings, fever, cough, and respiratory failure in a patient with AIDS, the positive predictive value for PCP is high (negative predictive values are high when BDG levels are low in this context) [25]. It is important to emphasize that this is not a specific test, and other fungal pathogens may present similarly with high BDG and respiratory failure.

The treatment of moderate to severe PCP is outlined in Table 76.1 [26]. Trimethoprim–sulfamethoxazole (TMP-SMX) is the preferred treatment for PCP in patients who have not had an adverse reaction to this drug [26]. Many physicians are willing to use TMP-SMX despite a history of a prior adverse reaction in patients receiving adjunctive corticosteroid therapy and ICU support, because it is not clear whether any of the alternatives is as effective for moderate-to-severe disease. Patients with severe PCP who do not respond, or who are intolerant of this medication are usually given pentamidine, but this drug is associated with adverse reactions that are more serious than those associated with TMP-SMX. Clindamycin with primaquine is effective for moderate-to-severe PCP, but primaquine cannot be administered parenterally, potentially limiting its use.

When treatment of PCP is delayed or ineffective, patients may develop hypoxemic respiratory failure. The clinical and radiographic features of severe PCP resemble the acute respiratory distress syndrome (ARDS), with hypoxemia, intrapulmonary shunting, reduced pulmonary compliance, and diffuse radiographic opacities [27]. As the disease progresses and pulmonary compliance diminishes, pneumothorax is common and is associated with a particularly poor prognosis [28,29] (Fig. 76.1). Just as severe PCP resembles ARDS clinically, the supportive treatment is similar, including intubation, mechanical ventilation, application of positive end-expiratory pressure, and lung-protective ventilation strategies [30].
Animal models of PCP indicate that the clinical severity of infection correlates more closely with markers of inflammation than with the organism burden, suggesting that the immune response and its attendant inflammation account for the clinical manifestations of pneumonia [31]. Respiratory compromise is believed to be mediated by activated CD8+ cells and neutrophils in the lung in response to killed organisms, and patients with PCP typically have deterioration of gas exchange during the first few days of treatment with anti-Pneumocystis agents alone [32]. When corticosteroids (administered as a taper described in Table 76.1) are administered to patients with moderate-to-severe PCP (defined as a PaO$_2$ less than 70 mm Hg while breathing room air or an arterial-alveolar oxygen difference greater than or equal to 35 mm Hg) at the start of anti-Pneumocystis treatment, there is a reduced likelihood of respiratory failure, deterioration of oxygenation, and death [33,34]. Corticosteroids may attenuate lung injury caused by the inflammatory response to killed organisms, allowing the patient to survive to receive more antimicrobial therapy. Corticosteroids offer no benefit for patients with less severe abnormalities in gas exchange at the start of therapy, or in whom they are administered more than 72 hours after anti-Pneumocystis treatment has begun.

Other Pulmonary Disorders
A wide variety of infectious and noninfectious HIV-associated pulmonary disorders may lead to respiratory failure. Bacterial pneumonias, most commonly caused by *Streptococcus pneumoniae*, have probably surpassed PCP as the cause of respiratory failure in the era of ART [35–37]. In patients with severe immune compromise, pulmonary infection or disseminated disease with *Pseudomonas aeruginosa, Mycobacterium tuberculosis*, cytomegalovirus, endemic fungi, and *Aspergillus* spp may also lead to respiratory failure [38]. Similarly, influenza-related morbidity and mortality are increased in severely immunocompromised patients. During active seasonal influenza cycles, empiric treatment with appropriate antivirals (e.g., oseltamivir) should be considered as diagnostic samples are acquired (e.g., nasopharyngeal swabs to detect respiratory viruses by PCR) [39].
CENTRAL NERVOUS SYSTEM DISORDERS

Because a substantial percentage of individuals with HIV present with advanced disease for reasons described earlier, other severe opportunistic diseases may require intensive care. Prominent among these are diseases of the central nervous system (CNS).

Meningitis caused by *Cryptococcus neoformans* often presents in a subacute manner, sometimes with headache and typical meningeal symptoms and signs, and occasionally with altered mental status thought to relate to elevated intracranial pressure (ICP) [40,41]. Infection is usually disseminated at the time of presentation with CNS disease, and there may be pulmonary and cutaneous manifestations as well. Given the tendency for elevated ICP to develop, imaging prior to lumbar puncture is generally recommended if cryptococcal meningitis (CM) is suspected. A lumbar puncture should include measurement of the opening pressure. Diagnosis is usually made by CSF analysis that includes cryptococcal antigen detection. Most often, the CSF will have a relatively low white blood (mononuclear) cell count, mildly elevated protein, and low glucose. A substantial minority will have a normal CSF profile. Features that are associated with severe disease and higher mortality are presentation with altered mental status, low CSF white blood cell count (<20 per μL), and high cryptococcal antigen titer (>1:1024) [42]. Treatment for severe disease is complicated by the tendency for elevated intracerebral pressure to develop. Repeated therapeutic lumbar punctures (LP) are sometimes required to improve clinical outcomes [43]. Treatment occurs in stages; the first stage is induction (duration ≥ 2 weeks), which involves infusion of an amphotericin B formulation together with oral flucytosine [44,45]. Close monitoring of renal function and CBC is necessary, given the toxicities of these agents. Therapeutic drug monitoring of flucytosine should be included, if available. With CM, the timing of initiation of ART is delayed because early treatment is associated with worse outcome [46,47]. Most clinicians wait until well after the induction stage of treatment of CM before starting ART (delaying ART initiation by 4 to 10 weeks). Later stages of CM treatment include consolidation with high-dose fluconazole for 8 weeks, and maintenance with lower dose fluconazole for 2 or more years following initiation of ART [48].

Focal encephalitis caused by *Toxoplasma gondii* most often presents with headache, altered mental status, seizures, and focal neurologic signs [49], occasionally requiring intensive care management. A diagnosis is made using a combination of imaging modalities and CSF sampling. MRI is the most useful, but findings usually cannot distinguish between toxoplasmosis, CNS lymphoma, or abscess; all may present with one or
more ring-enhancing lesions. A brain biopsy can establish the diagnosis, but lesions are often relatively inaccessible. If imaging suggests that lumbar puncture can be performed safely, CSF should be sent for *Toxoplasma* PCR, and studies to rule out other opportunistic diseases of the CNS (cytology, Epstein–Barr virus [EBV] PCR, *M. tuberculosis* PCR, cryptococcal antigen, JC virus PCR, etc.). Empiric treatment is often prescribed for patients with advanced immunocompromise, positive *Toxoplasma* serology, and characteristic CNS lesions. The treatment of choice is pyrimethamine and sulfadiazine, with leukovorin [50]. Individuals with sulfa allergies may be managed with clindamycin substituted for sulfadiazine. Adjunctive corticosteroids and/or anticonvulsants (see Chapters 81 and 151) may be needed in individuals with significant mass effect and/or presentation with seizures. With empiric treatment, a response should be expected within 2 weeks.

Other opportunistic diseases of the CNS observed with AIDS are lymphoma (usually EBV related) and progressive multifocal leukoencephalopathy (PML) caused by JC virus. These may present as severe disease, and treatment is largely supportive. In the case of PML, the optimal treatment is rapid initiation of ART. As immune reconstitution occurs in response to ART, CNS inflammation may worsen leading to clinical deterioration. Close monitoring and administration of corticosteroids may be required if there is paradoxical worsening of neurologic function.
Coinfection with HIV and Hepatitis Viruses

With improved treatment of HIV with antiretroviral agents, complications of hepatitis B (HBV) and C viruses (HCV) have emerged as a major cause of mortality for HIV-infected persons [51–53]. An estimated 15% to 30% of patients with HIV in the United States are coinfected with HCV, an eightfold increase in HCV infection compared with the general population [54]. Patients coinfected with HCV and HIV are more likely to develop cirrhosis than those with HCV alone [55]. Thus, many patients with HIV infection are admitted to ICUs with end-stage liver disease and associated encephalopathy and gastrointestinal hemorrhage.

A number of antiretroviral agents are also active against HBV, permitting construction of regimens effective against both pathogens for HIV–HBV coinfected patients. The management of coinfection with HIV and HCV entails separate combination drug regimens with interactions and overlapping toxicities. Recent advances in HCV treatment have improved the outlook for infected individuals, with cure rates well in excess of 90% in many studies. Direct acting antivirals (DAAs) now include inhibitors of the HCV protease, NS5a and NS5b (polymerase). Evolving recommendations require frequent updates to guidelines ([56] http://www.hcvguidelines.org). The treatment approach for HIV and HCV coinfected individuals is the same as for those with HCV infection alone; however, drug interactions with ART agents often limit options. Drug interactions with HCV-specific DAAs extend beyond ART agents, and careful review of medications is necessary for individuals receiving these agents during hospitalizations. Despite the high HCV cure rates, and relatively short and simplified treatment regimens, therapy continues to require close supervision by experienced specialists. Treatment with these agents may be associated with exacerbation of liver dysfunction and decompensation, particularly in individuals with advanced stages of cirrhosis (http://www.hcvguidelines.org).
Initiation of ART may be followed by paradoxical worsening of known opportunistic infections after an initial response to therapy, characterized by a robust inflammatory reaction. Alternatively, patients with an unrecognized infection, not yet manifested clinically, may develop an inflammatory reaction at the infected site (so-called unmasking). These reactions are not typical of the usual clinical presentation of the infectious agent, and are now termed “immune reconstitution inflammatory syndrome” (IRIS) or “immune restoration disease” \[57,58\]. For instance, *Mycobacterium avium* complex, which usually produces disseminated disease with no histologic evidence of host response in persons with advanced HIV infection and CD4\(^+\) lymphocyte counts <50 per \(\mu\)L, may present with fever and pain because of focal necrotizing lymphadenitis. A meta-analysis of 64 reports comprising 13,103 persons initiating ART found that 13% developed IRIS; some series report much higher rates, particularly in patients with cytomegalovirus retinitis \[16\]. The time to onset of IRIS is reported to vary from 3 to 658 days after starting ART, with a median of 29 to 49 days \[15–17,58\]. The risk is higher for patients with lower CD4\(^+\) counts before initiation of ART, but the occurrence of IRIS seems to correlate better with rapid decline in viral load than with increase in CD4\(^+\) lymphocyte count \[15,17\], and the meta-analysis found a case-fatality rate of 6.7% \[16\]. IRIS-related respiratory compromise is reported in association with mycobacterial infection and PCP \[59,60\]. Corticosteroids may be used to suppress the aberrant inflammatory reaction, but there are no guidelines as to when to use them or the optimal dose and duration. Corticosteroids are usually reserved for patients with severe inflammatory disease.
OTHER CRITICAL ILLNESSES

HIV-infected persons are not spared any of the diseases that can bring non–HIV-infected persons with otherwise similar characteristics to the ICU, including gastrointestinal hemorrhage, trauma, drug overdose, violence, and cardiovascular diseases. Injection drug users are obviously at increased risk of developing infective endocarditis. With advances made in ART, HIV-infected individuals can have a life expectancy that approaches that of uninfected individuals [61]. The usual diseases associated with aging are seen with increasing frequency as the HIV-infected population on effective ART grows older [62]. Some diseases of aging are seen with higher frequency among HIV-infected populations.

Patients with HIV infection have accelerated atherosclerosis and increased risk of coronary artery disease; this was previously attributed to therapy, particularly protease inhibitors which are known to increase plasma lipid levels [63,64]. However, the risk of major cardiovascular disease outcomes increased among patients randomized to interrupt ART when CD4+ lymphocyte count rose above 400 compared to those who continued therapy and who had more drug exposure [65]. Subsequent analyses have correlated cardiovascular disease risk to higher levels of viremia [66] and abnormalities of endothelial function that improve with ART [67].

Laboratory abnormalities, including pancytopenia, eosinophilia, and transaminase elevations, may either represent the patient’s baseline or indicate significant disease or drug toxicity. Among laboratory abnormalities that may safely be followed are macrocytosis as a normal accompaniment of zidovudine, stavudine, or tenofovir therapy (provided there are no hypersegmented polymorphonuclear leukocytes), mild indirect hyperbilirubinemia of patients on atazanavir or indinavir, and hyperuricemia of patients taking didanosine. Note that the use of stavudine, indinavir, and didanosine is increasingly rare, with the availability of less toxic alternative ART. Elevations of creatine phosphokinase in patients taking zidovudine or tenofovir may also be asymptomatic and benign, but some reflect clinical myositis caused by these drugs. Hyponatremia seems to be relatively common and well tolerated in advanced HIV infection, but frank adrenal insufficiency or isolated hypoaldosteronism may require specific diagnosis and management.
TOXIC EFFECTS OF ANTIRETROVIRAL THERAPY

The drugs used for ART are associated with several life-threatening toxicities that may prompt admission to the ICU. Older nucleoside analog reverse transcriptase inhibitors (NRTIs), especially didanosine and stavudine (and zalcitabine, which is no longer available in the United States), can cause pancreatitis, which may be severe. In a retrospective study of 73 HIV-infected patients with pancreatitis, 46% of cases were attributed to drug toxicity, with didanosine and pentamidine (used to treat PCP) the most common offending agents [68]. Didanosine may cause portal hypertension without cirrhosis [69]. Patients who received this drug even many years before may present with life-threatening hemorrhage from esophageal varices.

NRTIs can cause lactic acidosis by inhibiting DNA polymerase-γ, disrupting mitochondrial DNA. This may also cause hepatic steatosis or mitochondrial myopathy [70]. Lactic acidosis is the consequence of increased anaerobic glycolysis by damaged mitochondria, coupled with decreased lactate clearance by the fatty liver. Mild hyperlactatemia occurs commonly among patients receiving NRTIs and is not clinically important, but severe lactic acidosis occurs at a rate of 1.3 to 3.2 cases per 1,000 person-years of nucleoside exposure and may be life threatening [71,72]. The appearance of nausea, vomiting, abdominal pain, dyspnea, or weakness in persons on long-term therapy with these agents may herald the onset of this life-threatening illness and should prompt measurement of serum lactate. This entity should be considered in the differential diagnosis of apparent sepsis, hepatic failure, and pancreatitis requiring ICU admission of patients on ART. Because patients may also develop severe lactic acidosis as a result of sepsis, empiric antibiotics should be administered, pending the results of microbiologic evaluations. If severe hyperlactatemia or lactic acidosis is found, all ART must be stopped immediately because continuation of a partial regimen may lead to viral resistance. In addition to standard care, case reports suggest that this disorder may improve with use of riboflavin, thiamine, L-carnitine, and coenzyme Q [73–75]. The same drugs and mechanism underlie a syndrome of severe neuromuscular weakness and respiratory failure that may mimic Guillain–Barré syndrome or botulism, and the same
therapies have been proposed [76]. The newer NRTIs (tenofovir, emtricitabine, lamivudine, and abacavir) produce less inhibition of DNA polymerase-\(\gamma\) and have largely replaced the agents most commonly implicated (stavudine, didanosine, and zidovudine); this seems to have reduced the incidence of syndromes related to mitochondrial toxicity.

Abacavir hypersensitivity is a protean syndrome that may include fever, chills, nausea, diarrhea, rash, myalgia, aseptic meningitis, hepatitis, cough, or influenza-like illness within a few weeks of starting treatment. Discontinuation of the drug leads to resolution of symptoms, but rechallenge can produce an anaphylactic reaction with cardiovascular collapse and high fever [77,78]. This syndrome should be virtually eliminated by the introduction of screening for the HLA-B*5701 allele and avoidance of abacavir in persons who carry it [79,80].

Tenofovir nephrotoxicity rarely presents as Fanconi syndrome; with increases in serum creatinine, glycosuria, hypophosphatemia, and acute tubular necrosis. Electrolyte imbalance because of tubular dysfunction may be severe and require intensive repletion [81].

Severe rash, including Stevens–Johnson syndrome, is most notably associated with nevirapine, but can occur with other nonnucleoside reverse transcriptase inhibitors (NNRTIs) and rarely with protease inhibitors and NRTIs.
MANAGEMENT OF PROPHYLACTIC AND ANTIRETROVIRAL AGENTS

Even when critically ill, patients with advanced HIV disease who received prophylaxis against opportunistic infections like PCP before ICU admission should continue to receive it unless contraindicated. Initiation of appropriate prophylactic measures should be considered in those who have not. Judging whether prophylaxis is indicated may be difficult in acutely ill patients because of effects that stress, infections, and medications may have on CD4+ T-cell counts. Even a single dose of glucocorticoids can reduce the CD4+ T-cell count dramatically. In general, decisions regarding prophylaxis should be based on CD4+ T-cell values recently obtained, but prior to acute illness or receiving corticosteroids if they are available. In patients who stopped taking ART for more than a month, it is usually best to assume that the risk of a patient developing opportunistic infections corresponds to that before starting ART.

The use of ART for critically ill patients requires expertise in selection of drugs and consideration of their doses, toxicity, and interactions with other treatments. The critical care clinician is well-advised to manage these patients in close collaboration with an expert in antiretroviral treatment. Patients receiving ART should continue to receive these drugs whenever possible, because discontinuing therapy is associated with viral replication, emergence of resistance, and clinical progression of HIV infection. In patients coinfected with HBV, discontinuation of lamivudine (and presumably emtricitabine and tenofovir, the other antivirals active against HBV) may result in exacerbations of hepatitis B that may be fatal [82,83].

The feasibility of continuing ART depends on that of enteral administration. When the gastrointestinal tract is significantly dysfunctional, all of the drugs in a patient’s regimen will inevitably be stopped at the same time, and no harm is likely if they can be resumed in a few days. Still, the NNRTIs (efavirenz, nevirapine, and etravirine) are eliminated very slowly, and stopping all agents at the same time may lead to a prolonged period of inadvertent NNRTI monotherapy and selection for virus with drug resistance mutations. When ART therapy must be interrupted for more than a few days, consultation with an HIV specialist is recommended.

Continuing ART entails potentially complex interactions with other drugs prescribed, including effects on absorption and metabolism that
result in either suboptimal or toxic levels of both the antiretrovirals and other drugs. For example, administration of proton-pump inhibitors causes significant reductions in the protease inhibitor atazanavir; an H₂ blocker can be given safely 12 hours before or after atazanavir. Protease inhibitors significantly reduce the metabolism and increase the activity of midazolam. Lorazepam and temazepam may be safer alternatives for sedation, but dose titration with close monitoring of effect in the ICU setting may suffice to overcome the potential risks of midazolam administration. Given the frequency of cardiovascular disease as a cause of ICU admission among HIV-infected persons, HMG-CoA reductase inhibitors may be prescribed, but protease inhibitors have significant and varying interactions with most of these drugs; simvastatin and lovastatin are contraindicated with all of the protease inhibitors because of massive increases in their plasma levels.

The presence of acute kidney injury necessitates dose adjustments of all the nucleoside analogs except abacavir, and the components of fixed-dose combinations require individual adjustments. If renal function varies or is impaired for several days, the best way to assure consistently adequate and nontoxic levels of antiretrovirals is to change the regimen to drugs that do not require adjustment for renal insufficiency, when possible.

When considering whether to start ART for a critically ill patient who did not receive it before, a few questions may guide the decision. First, is the enteral route expected to remain available to permit consistent and continuous drug administration? If not, ART must wait. Second, does the patient have an infection for which there is no effective therapy other than the potential offered by improved immunologic status (e.g., cryptosporidiosis or PML)? In this situation, all other care is futile unless ART is begun, and it should be. Third, did the patient not receive ART because the diagnosis of HIV infection was never established, by choosing not to take ART because of personal reasons, or because of repeatedly opting to stop ART? The latter two do not lend themselves to easy answers, and it may be well to wait at least until the patient has decisional capacity and able to share in decision making. Patients with advanced neurocognitive disease may have marked improvement on ART and may regain functional independence; for them, treatment is as imperative as for those with otherwise untreatable infections. When therapy is started for patients who are deemed to be at high risk of abandoning it, the chosen regimen should have minimal adverse consequences if discontinued abruptly (e.g., NNRTIs should be avoided).

p. 717
p. 718
The risk of IRIS has been a deterrent to starting ART early for patients with opportunistic infection, but more recent studies have clarified this issue considerably. A randomized trial of early versus deferred ART in patients with acute opportunistic infections excluding tuberculosis found that fewer patients who received early therapy had progression of AIDS or death, with no difference in the rate of IRIS [84]. Other studies support a survival advantage for patients who started on ART in the ICU [85,86]. For patients with tuberculosis, IRIS occurred among 12.4% of patients randomized to early ART (started at a mean of 70 days after the initiation of antituberculous therapy) and only 3.8% of those whose ART was delayed until completion of treatment for tuberculosis (mean of 260 days), but mortality was significantly higher among the delayed ART group (12.1% vs. 5.4%), and no deaths were attributed to IRIS [87]. However, among patients with CM treated with a suboptimal fluconazole regimen that is the only one commonly available in Africa, early initiation of ART (within 72 hours of diagnosis) resulted in nearly threefold increased mortality compared to initiation after 10 weeks, with median survivals of 28 and 637 days, respectively [47]. Although firm conclusions are not yet available about the timing of ART in patients with serious opportunistic infections, it seems that the opportunistic infection should be under good control before initiating ART and that the clinician must anticipate the potential emergence of serious effects from IRIS [88].
PREDICTORS OF OUTCOME

Overall, it seems that critically ill patients with HIV infection have similar short-term outcomes as other patients with a comparable severity of illness, and survival rates seem to be improving [9–11,89,90]. Most studies in patients with HIV infection are limited by selection bias, because they are usually retrospective analyses where the admitting physician’s knowledge of the patient’s serostatus may have affected the decision to admit to ICU or the vigor or goals of care. In a study conducted in a South African surgical ICU, HIV testing was performed but results not divulged and there were no differences in ICU or hospital mortality or duration of stay when outcome was adjusted for age, despite a higher incidence of sepsis and organ failure in the HIV-infected patients [91]. Thus, evidence from a variety of settings supports the concept that HIV-infected and uninfected persons have similar outcomes of intensive care, and that decisions regarding the appropriateness of ICU interventions should not use HIV status alone as a criterion.

Studies examining the value of laboratory testing and scoring systems for predicting ICU outcomes of HIV-infected patients, including lactate dehydrogenase, serum albumin, CD4+ lymphocyte count, APACHE II score, and multisystem organ failure scores, yield conflicting data on their reliability. It now seems clear that patients with HIV/AIDS have similar short-term outcomes to those of other patients with a similar severity of illness. Long-term survival is related to the severity of the HIV disease, other comorbid illness, and whether the patient has been treated with ART. In addition to the patient’s illness, the experience of the hospital and healthcare providers with treating HIV-associated infections and managing complications also influences mortality. In one large study, adjusted mortality for patients with AIDS was 30% lower among hospitals with the most experience treating these patients [92].

Because the outcomes for intensive care do not depend directly on the patient’s HIV status, determination of whether or not a patient has HIV infection or determination of CD4+ lymphocyte counts should not be overriding considerations in deciding whether to offer or withhold intensive care. Rather, these decisions should be made using the same criteria as for all patients, namely, the likelihood of benefit and the patient’s values.
RISK TO HEALTHCARE WORKERS AND POSTEXPOSURE PROPHYLAXIS

Intensive care of patients carries an increased risk of exposure to bloodborne pathogens, including HIV. The risk of acquiring HIV-1 infection by mucous membrane exposure is approximately 0.09% (just under 1 in 10,000) and by percutaneous (e.g., needlestick) exposure, approximately 0.3%, or 1 in 300 instances [93,94]. Virtually all documented infections have involved accidents with hollow-bore needles. The risk is higher when inflicted by a device that came directly from the HIV-infected patient’s artery or vein, had visible blood on it, produced deep injury, or came from a source patient with terminal illness (defined as death because of AIDS within 60 days of the healthcare worker’s exposure). Each of these features increases the risk of infection independently. In a case–control study where healthcare workers infected by needlestick exposures were compared with healthcare workers who sustained exposures from HIV-infected patients but did not become infected, the only factor that was shown to reduce the risk of infection was postexposure use of zidovudine by the healthcare worker [95]. Zidovudine prophylaxis appeared to reduce the risk of infection by 81%. This study led to much stronger recommendations for ART for healthcare workers with percutaneous or mucous membrane exposure to HIV-1.

Current recommendations reflect the failure rate of single-agent postexposure prophylaxis, the prevalence of ART-resistant virus, the proven antiviral efficacy of three-drug regimens in infected individuals, and the importance of tolerability of the regimen to ensure completion of a full 4-week course [96]. The US Public Health Service now recommends three or more drugs for high-risk exposures from a known HIV-positive source. Examples of high-risk exposures include percutaneous injury involving a contaminated needle, or exposure to blood, tissue, or potentially infectious bodily fluid on mucous membranes or nonintact skin from patients with symptomatic HIV infection, AIDS, acute seroconversion, or known high viral load. The National Institutes of Health AIDS Information Web site (https://aidsinfo.nih.gov/) provides the most current drug recommendations and links to current PHS recommendations [96]. Expert consultation is advised, especially for cases involving drug-resistant virus, and pregnant or breastfeeding personnel. Recommendations for postexposure prophylaxis emphasize initiating treatment within an hour or two of exposure, and data from infants of HIV-positive mothers not treated during pregnancy and
delivery suggest little benefit to therapy delayed beyond 48 to 72 hours [97]. However, the time after which therapy will not be successful has not been defined.

The list of potential side effects of antiretroviral drugs is daunting, but newer regimens are better tolerated. Many healthcare workers receiving PEP will experience adverse effects, along with justifiable anxiety. They should be reassured that most HIV-infected people tolerate these regimens with the help of adequate psychosocial support and proper medical follow-up.
SUMMARY

In summary, the evolution of the AIDS epidemic and the continuing improvements of effective ART have changed the spectrum of critical illnesses for patients with HIV infection. The use of ART has led to reduced risk of AIDS-associated illness and improved survival, but raises new and complex questions about how best to use these treatments in patients with critical illness. Clearly, large-scale multidisciplinary studies of critical care of patients with HIV infection would yield valuable insights, but until the important clinical questions are answered, critical care clinicians must work closely not only with the ICU multidisciplinary team, but also with colleagues with backgrounds in infectious diseases, pharmacology, and palliative care. Advances in the management of opportunistic disease associated with HIV infection, based on randomized controlled trials or meta-analyses of such trials, are summarized in treatment guidelines that are maintained as living documents available to the public (https://aidsinfo.nih.gov) [26] and Table 76.2.

TABLE 76.2 Summary of Recommendations for Management of Complications of Human Immunodeficiency Virus Infection Based on Randomized Clinical Trials

- Early adjunctive treatment with corticosteroids reduces the risks of respiratory failure and death in patients with acquired immunodeficiency syndrome (AIDS) and moderate-to-severe Pneumocystis pneumonia [26,33,34].
- Combination treatment with amphotericin B and flucytosine versus fluconazole improves outcome in individuals with cryptococcal meningitis [44].
- Early versus delayed ART in patients with cryptococcal meningitis increases risk of death in patients receiving suboptimal treatment with amphotericin B and/or fluconazole [46,47].
• Early versus deferred ART in patients with acute opportunistic infections excluding tuberculosis decreases progression to AIDS or death, with no difference in the rate of IRIS [84].

• Early versus deferred ART in patients with tuberculosis decreases mortality, but increases risk of IRIS [87].

ART, antiretroviral therapy; IRIS, immune reconstitution inflammatory syndrome.

Drug abuse, the deliberate taking of an unprescribed drug dose or illicit substance, is a pervasive problem in our society [1]. A variety of drugs are abused, including opiates, depressants, stimulants, and hallucinogens. This chapter will focus on infections that occur as a consequence of drugs that are either explicitly illegal or those which are legal but are used by the patient for purposes other than for which they were prescribed. Abused drugs can be administered by a variety of means, including “snorting” through the nasal mucosa, via inhalation through smoking, orally, and by parenteral routes, including injection into the soft tissues, called “skin popping,” or directly into the vascular system.

Drug abuse is attended by an increased risk in a number of infections, some of which may lead patients to be admitted to the intensive care unit [2]. Infections associated with parenteral drug abuse include skin and soft tissue infection, endocarditis, bone and joint infections, pneumonia, ophthalmologic infections, and hepatitis [2–4]. Illicit drugs are often “cut” or mixed with adulterants, which may be contaminated with bacteria or may suppress the immune response—as is the case with agranulocytosis caused by levamisole-containing cocaine leading to bacterial or fungal infection [5]. Illicit drug injection occurs under unsanitary conditions using drugs that are not sterile and injection equipment that has often been used more than once. Such practices provide a mechanism for the passage of a variety of infectious agents. Although in some instances, particularly for the hepatitis viruses and human immunodeficiency virus (HIV), the infectious agent is passed directly from blood-contaminated drug paraphernalia to the patient, the mode of spread is less clear for other agents. Prevention of infectious complications of drug use is directed at treating addiction, or failing that, mitigating infectious complications via needle exchange programs [6]. Finally, many patients with substance abuse problems are homeless, have
poor nutrition, and live under crowded conditions, placing them at increased risk of tuberculosis (TB).

**FEVER**

Fever is one of the most common complaints of parenteral drug users presenting to the hospital. Self-limited illnesses are the most common causes of fever in this population. More significant etiologies include pneumonia, cellulitis, and soft tissue abscesses. Endocarditis accounts for fewer than 15% of all cases of fever [7].

All febrile parenteral drug users should undergo a thorough history, physical examination, and have routine blood laboratories and chest radiographs taken. Particular attention should be paid to abnormalities of the skin and soft tissues, cardiac valvular abnormalities, bony tenderness, and pulmonary abnormalities. However, clinical evaluation alone often does not differentiate major disease from trivial illness in these patients. Parenteral drug users who are febrile should be admitted to the hospital for further observation.

Weisse et al. [7] have developed an algorithm for febrile parenteral drug abusers with no apparent source of infection. In this approach, blood cultures are obtained from all patients and empiric antibiotic therapy is started. If blood cultures are positive or if the patient has clinical stigmata indicative of endocarditis, an echocardiogram is performed. If valvular vegetations are seen, the diagnosis of endocarditis is considered established. On the other hand, if blood cultures are negative and the patient is clinically well, antibiotic therapy may be discontinued. However, parenteral drug users commonly self-administer antibiotics and this practice may substantially reduce the likelihood of positive blood cultures, as can prophylactic antibiotics in HIV+ patients [8]. Hence, careful clinical evaluation is advised when making antibiotic decisions for these patients.
BACTEREMIA

Bacteremia is a frequent occurrence among febrile parenteral drug users [9]. Approximately 60% of bacteremias in parenteral drug abusers are due to causes other than endocarditis [10]. Of these, the majority are caused by either skin or soft tissue infections or to mycotic aneurysms of peripheral arteries. A smaller number of bacteremias result from miscellaneous causes, such as septic arthritis, septic thrombophlebitis, or pneumonia. In about 3% of cases, the source of the bacteremia is undiscovered.

Although the organisms associated with bacteremias among parenteral drug users may vary based on geographic location and the type of drug abused, some generalizations can be made [10]. Drug users have an increased incidence of staphylococcal carriage of the skin, nose, or throat. Bacterial infection derives principally from the user’s own flora, so that Staphylococcus aureus constitutes the majority of bacteremias among these patients. In this regard, methicillin-resistant S. aureus (MRSA) infections are now being encountered with increasing frequency in parenteral drug users and in the community [11,12].

Streptococci and Gram-negative aerobic bacilli are the next most frequently isolated organisms. Polymicrobial bacteremias occur in about 10% of cases, and in about two-thirds of these cases at least one of the organisms isolated is a Staphylococcus spp. Bacteremia and other infections caused by the facultative anaerobe Eikenella corrodens are particularly associated with injecting drug users (IDUs) who contaminate the injection needle or the injection site with saliva [10,13].

The approach toward the bacteremic parenteral drug user should be to search for an underlying etiology and to begin empiric antibiotic treatment. The isolation of a group A β-hemolytic streptococci from the blood should prompt a search for a cutaneous or soft tissue focus of infection [14]. Empiric antibiotic therapy may be based on local antimicrobial sensitivities but should generally include agents directed against staphylococci and streptococci as well as aerobic Gram-negative bacilli. If MRSA infections have previously occurred among parenteral drug users in the community, vancomycin should be considered.
SOFT TISSUE INFECTIONS

Skin and soft tissue infections occur commonly in the parenteral drug user and are increasing in frequency [15,16]. Such infections are often polymicrobial and appear to derive from either the skin or oral cavity. The most common pathogens are S. aureus, streptococci, oral anaerobes, and aerobic Gram-negative bacilli [13–17]. Cutaneous infection in the intravenous drug user generally occurs in the antecubital fossa, forearm, and hand as these are the sites of the most accessible veins. However, intravenous drug users may also avail themselves of other, less available sites with infection occurring in the feet, legs, anterior neck, groin, and axilla [18,19].

The most common skin infections among IDUs are simple cellulitis and localized skin abscess. These occur more frequently among those who “skin pop” compared to those who inject intravenously [20]. Simple cellulitis usually requires only antibiotic therapy directed against staphylococci and streptococci. IDUs are particularly at risk of MRSA infections of the skin and soft tissues [11]; patients requiring intravenous therapy should receive vancomycin. Localized soft tissue abscesses that do not penetrate into the deep subcutaneous tissue should be drained. Given the risk of occult bacteremia for this population, antibiotic therapy should be given as directed by Gram stain of the drained material. In all patients with a history of injection drug use, blood cultures should be obtained as part of the workup of skin and soft tissue infections.

The presence of vesicles or bullae, an area of central necrosis within a larger area of erythema, and the presence of subcutaneous crepitation in a patient with systemic toxicity is suggestive of necrotizing fasciitis [21]. Gas seen in the soft tissues on radiographs is also indicative of deep infection [22]. However, extensive necrosis may be present even in the absence of these signs, and surgical exploration should be considered in any case that manifests local erythema, fluctuance, and induration [21]. Suspicion for needles or other foreign bodies should similarly prompt surgical exploration. Any abnormal material from this exploration should be immediately examined using Gram stain to provide the basis for empiric antimicrobial therapy. Examination of a sample of tissue using frozen-section biopsy may also be useful [23]. Magnetic resonance imaging (MRI) typically reveals increased T2 signal along fascial planes and gadolinium enhancement, whereas contrast-enhanced computed
tomography (CT) scanning is a less sensitive diagnostic tool for necrotizing fasciitis [22].

Necrotizing fasciitis, pyomyositis, or gangrene requires immediate, aggressive debridement in the operating room in association with parenteral antibiotics [21]. Gram stain and culture are imperative to guide antimicrobial therapy. Empiric therapy should be directed against staphylococci, streptococci, anaerobes, and aerobic Gram-negative bacilli. Surgical debridement may be required on multiple occasions before the infection is controlled. There have been multiple outbreaks of soft tissue infection with or without systemic symptoms associated with Clostridium spp. discussed later in this chapter.
PERIPHERAL VASCULAR INFECTIONS

Because parenteral drug use often involves vascular injection of material under nonsterile conditions, it is not surprising that a wide range of vascular complications may result from these practices [24]. The most frequent manifestations of such infections are fever associated with pain, redness, and swelling over the involved area. When the injecting site is into the deep tissues of the groin or neck, it may be difficult to distinguish involvement of vascular structures from simple cellulitis, soft tissue abscess, or fasciitis. If there is any question, angiography should be performed to determine if vascular tissue is involved. Septic thrombophlebitis usually presents as fever, bacteremia, and swelling over the involved vein. This can often be treated with antibiotics alone, although incision, drainage, and removal of the vein are sometimes necessary. Anticoagulation is generally not required [10].

Mycotic aneurysms result when the user injects directly into the artery [10,24]. Aneurysms most frequently occur in the femoral arteries. Carotid aneurysms and brachial artery aneurysms occasionally occur [24]. The classic presentation of this syndrome is a febrile patient with a tender, pulsatile mass, usually in the groin or the neck. Sometimes, there is a small amount of bleeding at the site. If there is any question of an aneurysm, a vascular surgical consultation should be obtained prior to any exploration of the lesion. Angiography will confirm the site and extent of the aneurysm. The most frequent microbiologic agents isolated are *S. aureus* and streptococci, with aerobic Gram-negative bacilli occasionally being identified [10]. Empiric antibiotic therapy should be directed against these organisms. Ligation and excision of the involved arterial segment is usually successful [25].
ENDOCARDITIS

Endocarditis in the parenteral drug abuser differs in several respects from endocarditis in the nonaddict. It is more likely to occur in persons without underlying valvular heart disease, to involve the tricuspid valve, to be caused by *S. aureus*, and to have a more benign outcome [3,26]. Certain types of intravenous drug abuse may predispose to the development of endocarditis. Heroin use has long been associated with this complication.

Tricuspid valve endocarditis is the prototypical presentation of endocarditis in the parenteral drug user [27]. The patient complains of fever, usually for less than 1 week. There may be a history of chills and pleuritic chest pain and occasionally hemoptysis. On physical examination, fever is a nearly universal finding. A systolic murmur may or may not be present on admission, but often develops during the course of therapy. Signs of peripheral embolization, such as petechiae, splinter hemorrhages, Janeway lesions, or Roth spots, are uncommon. Osler’s nodes are frequently absent. On chest radiograph, multiple patchy infiltrates indicative of pulmonary emboli are strongly suggestive of the diagnosis of tricuspid endocarditis. Blood cultures are usually positive and in the majority of instances, *S. aureus* is isolated. When blood cultures are negative in the face of the appropriate clinical syndrome, one should suspect that the patient has recently taken antibiotics.

Endocarditis involving the valves of the left side of the heart may also occur in the parenteral drug user. Compared to patients with tricuspid valve endocarditis alone, there is more likely to be a history of underlying heart disease [10]. On examination, a heart murmur is usually evident on presentation, and peripheral emboli are frequent. Streptococci are more likely to be isolated from the blood, but *S. aureus* is still frequently isolated [3,10,27].

In addition to staphylococci and streptococci, a variety of other organisms have been associated with endocarditis in the parenteral drug user, including aerobic Gram-negative bacilli, particularly *Pseudomonas aeruginosa*, and fungi, notably *Candida* spp. [3]. Moreover, polymicrobial bacteremia is a well-recognized complication of endocarditis in this population and is usually indistinguishable on clinical grounds from that caused by a single organism [28].

Bacteremia and pulmonary emboli on chest radiograph are highly predictive of tricuspid valve endocarditis among parenteral drug users [3,10]. However, all individuals with clinically suspected endocarditis should have echocardiography performed. Transesophageal echocardiography is more sensitive than transthoracic echocardiography
in identifying valvular vegetations [29]. When echocardiographic findings are combined with clinical manifestations, the diagnosis of endocarditis can usually be established with high sensitivity and specificity using the Duke criteria or modifications of the Duke criteria, even among IDUs with HIV infection [30].

Empiric therapy for endocarditis of the parenteral drug user should be directed against staphylococci, streptococci, and, rarely, aerobic Gram-negative bacilli. Nafcillin, oxacillin, and cefazolin are reasonable choices only if methicillin resistance among staphylococci has not been encountered. Vancomycin is the current alternative for the treatment of MRSA infections and for the β-lactam–allergic patient.

The prognosis for tricuspid valve staphylococcal endocarditis of the parenteral drug user is good, with a mortality of less than 10% employing a choice of several therapies [3,10,30]. There was no difference of outcome between treatments with a β-lactam antibiotic alone and in combination with an aminoglycoside for 4 weeks [31]. Although a combination of a penicillinase-resistant penicillin with an aminoglycoside has been advocated for 2-week therapy for right-sided endocarditis [32], one study found that results for combination therapy were no different from those when a penicillinase-resistant penicillin was used alone [33] (see Table 77.1).

Nonstaphylococcal endocarditis, particularly that involving the aortic and mitral valves, has a significantly worse prognosis. Left-sided endocarditis secondary to *P. aeruginosa* has a particularly poor outcome, with a mortality rate of nearly 70% [10]. To achieve cure, a 6-week course of intravenous therapy with an antipseudomonal β-lactam antibiotic plus an aminoglycoside, both at high doses, combined with early surgical removal of the involved valve is usually required [34]. *Candida* endocarditis also has an extremely high mortality rate even with prompt valve replacement and systemic antifungal therapy [35].

The role of surgery for endocarditis of the parenteral drug user is no different from endocarditis in the general population. Hemodynamic decompensation, persistently positive blood cultures in the face of appropriate antimicrobial therapy, multiple embolic episodes after therapy is initiated, fungal endocarditis, and evidence of extravascular extension of infection constitute major criteria for valve replacement [36]. Tricuspid valvulotomy is successful in the majority of patients with
isolated tricuspid valve involvement and intractable infection. Only about 10% of patients require a subsequent prosthetic valve to control congestive right-sided heart failure [37].
SKELETAL INFECTIONS

Infections of the bones and joints represent a distinct clinical syndrome in the drug abuser. Most cases have been reported among intravenous heroin users, and many cases occur in association with endocarditis [38]. Bacterial osteomyelitis of the vertebral column is the most frequent skeletal infection reported. The lumbar, cervical, and thoracic spine are involved, in that order. Patients generally present with weeks to months of pain in the involved area. High fevers are unusual, and many patients are afebrile. There is usually tenderness over the involved vertebral bodies and radiographic evidence of osteomyelitis. Laboratory values are generally normal, although the peripheral white blood cell count may be modestly elevated. The erythrocyte sedimentation rate and/or C-reactive protein are almost always elevated and may serve as useful markers of a response to therapy [39]. Because of the chronicity of symptoms and the general lack of toxicity of these patients, it is not unusual for the diagnosis to be missed for weeks or even months. The complaint of low back or neck pain in an intravenous drug user should always suggest the diagnosis of vertebral osteomyelitis. Septic arthritis often involves the sacroiliac and sternoarticular joints and the symphysis pubis. There is usually weeks to months of pain at the site and tenderness to palpation at the site of involvement. Radiographs are usually normal at presentation. MRI is preferable to contrast-enhanced CT of the spine to make the diagnosis of vertebral osteomyelitis [40].

The bacteriology of skeletal infections among drug users is quite different from that seen in other patients. Gram-positive cocci, such as staphylococci and streptococci, are frequently isolated, as well as aerobic Gram-negative bacilli, particularly P. aeruginosa [38]. Skeletal infections caused by Candida spp. may also occur, either alone or as part of a dissemination syndrome [41]. Because of this, it is imperative that a bacteriologic diagnosis be established in such patients. In most cases, this can be achieved by needle aspirate of the involved bone or joint. For sternoarticular infections, open surgical exploration is often required. Therapy involves long-term antibiotic therapy and in some cases surgical debridement [42].
Anaerobic spore-forming bacilli of the genus *Clostridium* are ubiquitous in the environment; exospores can remain viable indefinitely. If illicit substances become contaminated with these spores, subsequent injection of the substances may result in severe illness or death. The first reports of infections in people addicted to morphine injection were of tetanus in 1876. By the 1950s in New York, drug addiction accounted for the majority of cases of tetanus. Wound botulism caused by *Clostridium botulinum* was first observed in IDUs in the United States in 1982. Cases increased during the 1990s with the use of black-tar heroin, and a similar outbreak was seen in Germany in 2005. These patients presented with abscesses associated with symmetrical descending paralysis, some requiring mechanical ventilation. Treatment included antitoxin, antimicrobials, and surgical drainage of abscesses [43]. In the last decade, there have been outbreaks of serious illness and death among IDUs in the United Kingdom due to *Clostridium novyi* and *Clostridium histolyticum* [44]. Skin poppers using subcutaneous and intramuscular injection appear to be particularly at risk [45].

Similar to infections with *Clostridium* spp., since 2009, there have been cases of anthrax confirmed in heroin users in Scotland [46]. All injection routes have been implicated, but smoking or snorting may also pose a significant risk. Most had severe soft tissue infections with significant soft tissue edema but differed from classic necrotizing fasciitis or classic cutaneous anthrax. Patients had vague prodromal symptoms, appeared very ill, but their symptoms had nonspecific systemic features. Some developed septic shock leading to multiorgan failure.
Injecting drug use represents the third most common risk behavior for infection with HIV in the United States and is associated with 75% of HIV cases among heterosexual men. Black and Hispanic ethnic groups are disproportionately represented among IDUs with HIV infection [47]. In some metropolitan regions, notably Atlanta, Detroit, and San Francisco, the rate of HIV infection among IDUs is approximately 10%. There is great geographic variability in the prevalence of HIV infection among IDUs. The highest rates are in the northeastern United States and Puerto Rico.

Certain practices increase the risk for a drug user to acquire HIV infection. These include frequent intravenous drug injections, injection in “shooting galleries,” places where users rent the injecting paraphernalia and return it after use, injection with used needles, or sharing needles. Additional factors associated with an increased risk include use of cocaine or other drugs that prompts HIV risk behaviors and having sex partners who use intravenous drugs. The latter is significantly associated with HIV infection in women [48]. Finally, the use of methamphetamine, “crystal meth,” has been linked to an increase in the sexual transmission of HIV, including highly antiretroviral-resistant strains [49]. In vitro studies show that opiates, methamphetamine, and cocaine can potentiate HIV replication and can enhance neurotoxicity [50].

HIV-positive IDUs are more likely to develop infections that are not AIDS-defining illnesses. Disease patterns in this group may differ from the other HIV-infected groups [51]. In particular, they have a high risk of developing bacterial pneumonia and bacterial sepsis, especially because of encapsulated organisms such as *Streptococcus pneumoniae* or *Haemophilus influenzae*. This observation highlights the importance of pneumococcal and *H. influenzae* type B vaccines in this group. Progressive decline of CD4 lymphocyte counts to less than 200 per μL, and smoking illicit drugs significantly increase the risk of bacterial pneumonia [52]. In one study, *Pneumocystis* pneumonia, community-acquired bacterial pneumonia, and TB were the three most frequent pulmonary diseases seen among a group of illicit drug users in Washington, DC [53].

Any intravenous drug user should be considered at risk of HIV infection, and such patients should be offered testing for infection [47]. In addition, one study demonstrated the effectiveness of preexposure prophylaxis with daily administration of tenofovir in IDUs, although
public health authorities suggest that emtricitabine be coadministered with tenofovir for HIV prophylaxis in IDUs ([54], see Table 77.1). In areas of high prevalence, the clinician should be aware that HIV-related immunodeficiency might be complicating the clinical course in an IDU. In the United States, IDUs are also the highest risk group for human T-cell lymphotropic virus type I or II (HTLV-I or HTLV-II) infection [4]. The impact of this on HIV-related mortality is unclear, but coinfection with HIV and HTLV-I has been associated with myelopathy [55].
Acute and chronic hepatitis have long been recognized as common reasons for hospital admission among drug users [4]. Of the infectious causes, hepatitis B virus (HBV) remains a principal pathogen. It is estimated that from 60% to 80% of parenteral drug users in the United States are infected with hepatitis B, and that nearly 10% are chronic carriers [56]. Moreover, coinfection with the hepatitis delta virus, a hepatotropic agent that requires hepatitis B for replication, has been reported in 8% to 40% of IDUs infected with hepatitis B and is associated with a more fulminant course [57]. Hepatitis A has also been documented as a cause of acute hepatitis among intravenous drug users [58].

After HIV infection, infection with hepatitis C virus (HCV) is the next emerging infectious disease epidemic in the United States. The vast majority of cases of HCV infection are associated with injecting drug use. Acute infection, which occurs relatively soon after injection drug practices begin, is rarely symptomatic, but chronic infection occurs in about 85% of all infections. A subset of patients may develop chronic liver disease, cirrhosis, and hepatocellular carcinoma. Recent studies report a decrease in HCV seroprevalence among IDUs from 65% to 35% [59]. Parenteral drug abusers may suffer multiple attacks of acute hepatitis and are also likely to have significant structural and functional abnormalities of their liver, even if they are asymptomatic. Noninfectious factors, particularly the use of alcohol and other drugs, may act synergistically with the hepatitis viruses to lead to a poorer outcome [56].

Concomitant HCV and either HBV or hepatitis A virus (HAV) can lead to severe hepatitis or death, underlining the importance of vaccinating eligible parenteral drug users for HAV and HBV [60]. Special attention is required to choose therapies in patients with HIV and HBV coinfection. Antiretroviral medications like lamivudine or tenofovir are only partially active as monotherapy against both viruses, requiring thoughtful combination therapy to be effective against both viruses. There is an increase in the incidence of hepatocellular carcinoma and hepatotoxic effects associated with antiretroviral drugs in patients with HIV and HCV/HBV coinfection [61]. Newer, interferon-free oral HCV therapies are becoming available to cure HCV infection in 12 to 24 weeks in IDUs and potentially halt the HCV epidemic [62].

Prevention services recommended for injection-drug users include
annual testing for HIV infection, hepatitis A vaccination, accelerated hepatitis B vaccination, and testing for HCV infection [63,64].

Sexually Transmitted Diseases

Sexually transmitted infections such as Chlamydia and gonorrhea are closely associated with substance abuse, both because of frequent exchange of sex for money or drugs and because of the sexual disinhibition that result from the use of psychoactive substances, especially alcohol and cocaine. Freebase (“crack”) cocaine use has also been linked to an increased risk of syphilis and other ulcerative genital infections [65]. The high false-positive rate of nontreponemal tests for syphilis (rapid plasma reagin test and the Venereal Disease Research Laboratory test) in IDUs requires use of specific treponemal tests (e.g., the fluorescent treponemal antibody absorption test). Standard therapy for syphilis appears to be effective in both HIV-seropositive and HIV-seronegative IDUs. HIV-infected women have higher risk of cervical dysplasia and cancer associated with concurrent human papillomavirus infection that warrants at least yearly Papanicolaou smears in this group [51].
PULMONARY DISEASE AND TUBERCULOSIS

As noted earlier, community-acquired pneumonia, TB, HIV-associated *Pneumocystis* pneumonia, and septic pulmonary emboli caused by right-sided endocarditis are the major pulmonary complications of illicit drug use [10,53]. In addition, pulmonary edema may acutely attend drug injection. This is not associated with infection and usually clears in 1 to 2 days.

A unilateral infiltrate on chest radiograph in a drug abuser should suggest a bacterial pneumonia. Antibiotic therapy should be directed against community-acquired pathogens, such as *S. pneumoniae*, *S. aureus*, and nonpseudomonal Gram-negative bacilli, such as *H. influenzae* and *Klebsiella pneumoniae*. If there is a recent history of unconsciousness suggesting aspiration of oropharyngeal contents, antimicrobial therapy directed against anaerobes should be considered.

Nearly one out of three U.S.-born persons older than 15 years of age who has TB is a substance abuser. In addition to poor socioeconomic condition, substance abuse often takes place in enclosed spaces with poor ventilation and high volumes of human traffic, and increases the likelihood of TB transmission [66]. The risk of developing active TB among IDUs is significant, particularly if they are coinfected with HIV. Many drug users with HIV infection and TB may not demonstrate cutaneous tuberculin reactivity probably because of anergy. These patients have a high risk of developing active TB that is more likely to be extrapulmonary [67]. Data indicate the effectiveness of preventive isoniazid therapy for all drug users who are HIV infected and live in areas of high prevalence of TB [68]. Some experts advocate treatment of latent TB regardless of tuberculin skin test reaction, but the spread of multidrug-resistant TB in HIV+, drug-using populations suggests that this approach may not always be successful [69].

The clinician should maintain a high index of suspicion of TB in any drug user with pulmonary disease, particularly if the patient is infected with HIV. If there is any possibility of pulmonary TB, patients should be placed in respiratory isolation. Acid-fast smears should be performed on at least three respiratory specimens before active pulmonary TB is ruled out. If smears are positive, antituberculous therapy should be initiated [70] (see Chapter 82). Clinicians must address barrier to treatment adherence to reduce the risk of treatment failure that will lead to developing drug resistance [51].
DISSEMINATED CANDIDIASIS

A distinctive form of disseminated candidiasis has been described in injecting drug abusers who use brown heroin. *Candida albicans* has been specifically implicated in these cases. The source of infection is unclear but appears to be derived from the drug user’s own flora. The syndrome is characterized by fever within hours after injection, followed days to weeks later by skin, eye, and osteoarticular lesions. The skin lesions consist of deep subcutaneous nodules confined to the scalp or other hairy areas, and painful pustules on an erythematous base found in all areas of the body. Direct examination of expressed material from these pustules will demonstrate budding yeast. Costochondral tumors are a unique part of the syndrome, presenting as pain and swelling over the involved ribs. Biopsy of such lesions is often diagnostic, demonstrating both pseudohyphae and yeast. Optimal therapy is not established. Azole antifungals have been used successfully in many cases of skin involvement alone, but amphotericin B or surgery has been required with ocular or osteoarticular involvement [71].
OCULAR INFECTIONS

IDUs have an increased risk of eye infections, usually secondary to hematogenous spread from another site. Most cases are secondary to *Candida* spp., either as part of the disseminated candidiasis syndrome described earlier or with eye involvement alone. *Aspergillus* and *Fusarium* spp. have also been associated with endophthalmitis in the parenteral drug user. Usually only one eye is involved, and there are no other sites of infection. Treatment generally requires vitrectomy combined with systemic antifungal therapy such as voriconazole or amphotericin B.

Endophthalmitis due to bacteria is far less common than that due to fungi. Unlike fungal endophthalmitis, which often presents indolently, the onset of bacterial endophthalmitis is usually explosive with acute pain, redness, and decreased visual acuity. It may be mistaken initially for conjunctivitis. Progressive destruction of the eye may occur rapidly and immediate ophthalmologic consultation is requisite. Unusual organisms have been frequently isolated in this disease, such as *Bacillus* spp. and *Staphylococcus epidermidis* [72].
Epidural abscess is the most frequent central nervous system infection in IDUs. A common presentation is indolent radicular pain associated with an underlying vertebral osteomyelitis. Imaging studies, such as myelography, CT scan, or MRI, are useful in defining the extent of the infectious process. Needle aspiration under radiographic visualization can establish the microbiologic etiology. Staphylococci are the most frequent cause, although other pathogens, including *P. aeruginosa* and *Mycobacterium tuberculosis*, have also been recognized. Neurosurgical consultation should be obtained at the time the diagnosis is first suspected [2,73].

Brain abscesses may occur, usually as a result of embolization from either endocarditis or a mycotic aneurysm. They are usually multiple and generally caused by *S. aureus*. Antibiotic therapy alone has led to cure in some cases [74]. Cerebral mucormycosis is another complication of intravenous drug use and is suggested by the finding of lesions in the basal ganglia [75].

Chapter 78

Infective Endocarditis and Infections of Intracardiac Prosthetic Devices

SARAH H. CHEESEMAN • KAREN C. CARROLL • SARA E. COSGROVE

Infective endocarditis (IE) is an infection of the endothelial lining of the heart, characterized on pathologic study by vegetations. The infected site is usually a valve, but endocarditis may be situated on mural thrombi (rare) or the endothelial surface on which the jet stream from a stenotic lesion (patent ductus, ventricular septal defect, or stenotic valve) impinges. The term encompasses infection of the endothelial surface of any blood vessel, which most frequently occurs on hemodynamically or structurally abnormal ones such as abdominal aortic aneurysms, arteriovenous fistulas, and prosthetic grafts. The peculiarities of these infections are beyond the scope of this chapter, but the general principles of diagnosis and treatment are the same.

Significant changes in the epidemiology and character of IE have been noted since 1990 [1–10]. Shifting demographics, an expanding pool of elderly, chronically ill and immunocompromised patients, and rising rates of nosocomial bacteremia have been observed [1–10]. Unanticipated increases in societal behaviors that predispose to bacteremia, such as injection drug use, body art (including piercing and tattooing) [11], and acupuncture [12], have also contributed to the steady incidence of IE. All of the above have contributed to changes in the microbiology of IE [1–10]. Simultaneously, advances in diagnostic criteria and methods and improvements in cardiothoracic surgery have occurred. Taken together, there has not been a noticeable decline in either the incidence of or the mortality from IE [1–10].

Among published series of more than 100 patients between 1994 and 2008, reported mortality ranged from 10% to 37% [1–4,9,10], with the
lowest mortality rates attributed to earlier and higher rates of surgery, short delay before treatment, or high doses of bactericidal drugs. Decline in mortality has occurred predominantly among young patients. Mortality remains high for the elderly [2,3,10,13], diabetics [14], patients with other predisposing diseases such as chronic renal failure requiring hemodialysis and immunosuppression [1,2,9,10,15–18], patients with discernible valvular vegetations [16], patients with healthcare-associated infections [10,17], and those infected with staphylococci, particularly methicillin-resistant *Staphylococcus aureus* (MRSA) [2,8,10,16,19].

Traditionally two clinical forms of endocarditis have been delineated: acute and subacute. Subacute disease denotes insidious onset, with slow development of the characteristic lesions and absence of marked toxicity for a long period. A high proportion of these cases occur on previously damaged valves and many are caused by organisms of relatively low virulence, such as α-hemolytic streptococci (viridans streptococci). In contrast, acute bacterial endocarditis presents as a fulminant infection, with abrupt onset, high fever, more frequent leukocytosis, and rapid downhill course with respect to both valve destruction and systemic toxicity. This is most frequently secondary to *S. aureus* and may occur on previously normal valves. Among patients who require intensive care, the acute form of infection will be the more frequent problem.

A classification that more accurately characterizes current trends in IE has been proposed [6]. Dividing IE into four major categories as follows may provide better delineation of clinical conditions and microbial pathogens [6]. These categories are (a) native valve endocarditis (NVE); (b) prosthetic valve endocarditis (PVE)—early (<12 months following surgery) and late (>12 months following surgery); (c) IE in the injection drug user; and (d) nosocomial IE.

All observers of IE have noted a decrease in the frequency of rheumatic heart disease as a predisposing lesion and an increase in degenerative diseases [3,6,7,9] and other previously unrecognized conditions such as mitral valve prolapse and idiopathic hypertrophic subaortic stenosis [15,16]. Taking these trends together, the universal observation of an increasing proportion of cases among older age groups is not surprising. The incidence of IE is higher among men compared with women among patients younger than 65 years and has remained relatively stable over the last several decades. In contrast, the incidence among women has significantly increased since 2000, especially among the elderly (>65 years) [8,9,13].

Populations particularly at risk of endocarditis are injection drug users
and patients with prosthetic valves. Since the 1990s, other populations at risk have increased: transplant recipients [20,21], burn patients [22], patients with medical devices that put them at risk of bacteremia [9,17,23,24], and, most notably, persons on chronic hemodialysis [17,18,25,26].

Problems of endocarditis particularly relevant to patients in cardiac or intensive care units (ICUs) include the following:

1. Acute bacterial endocarditis,
2. Prosthetic valve endocarditis,
3. Endocarditis in patients with intravascular foreign bodies, such as pacemakers and indwelling vascular catheters,
4. Indications for surgery for endocarditis.

ETIOLOGY

The term infective endocarditis properly includes the whole world of microorganisms that can cause the disease. Fungi, rickettsiae (Coxiella burnetii, which causes Q fever), Chlamydia sp., and perhaps even viruses have been implicated in endocarditis, although bacteria are still the predominant cause. Substantial advances in the isolation of microorganisms and improvements in serologic testing and molecular detection have widened the spectrum of causative organisms. Uncommon species of streptococci, emerging pathogens such as Bartonella sp. and Tropheryma whipplei, the increase in fungal pathogens among nosocomial cases and immunocompromised patients, and increasing resistance among “typical” endocarditis pathogens such as enterococci present unique diagnostic or therapeutic challenges [5,6,17,20–23,26].

Table 78.1 summarizes the most common pathogens from a large series of endocarditis cases that occurred between 1985 and 2005 [1–4,6–9,15,27–30]. Series with a large number of injection drug users [1,6,15,19,28], patients on chronic hemodialysis [1,2,10,18,23], transplant recipients [20,21], and those reporting healthcare-associated IE [1,6,7,10,17,23,24,26] tend to report more cases caused by S. aureus. Viridans streptococci occur more frequently but no longer predominate among non-injection drug user populations and the elderly [9]. Identification to species level among the viridans streptococci may have important therapeutic and prognostic implications. The Streptococcus anginosus (milleri) groups (S. anginosus, S. constellatus, and S. intermedius) are frequently associated with abscess formation and tend to cause severe disease but cause endocarditis less often than other
viridans streptococci [31,32]. S. anginosus is the least likely among the three species to cause abscesses and the most likely to be associated with endocarditis [32,33]. The nutritionally deficient streptococci include the following genera and species: Abiotrophia defectiva, Granulicatella adiacens, Granulicatella para-adiacens, Granulicatella balaenopterae, and Granulicatella elegans [34,35]. Together these organisms constitute 3% to 5% of cases of endocarditis caused by viridans streptococci [35]. These organisms require pyridoxal, the active form of vitamin B₆, for growth. Unlike other species of viridans streptococci, these organisms are tolerant to penicillin, and at least one series [34] has found decreased susceptibility to penicillin, extended-spectrum cephalosporins, and macrolide antibiotics. High relapse rates are described especially when patients are treated with penicillin alone [35]. Most cases of viridans streptococcal endocarditis (80%) are caused by Streptococcus sanquis, Streptococcus mitis, or Streptococcus mutans [15,19,30,31]. There do not appear to be any statistically significant differences in the symptoms, demographics, or complications among patients with infections caused by this group of organisms. Newer species of viridans streptococci continue to be described.

**Notes:**

- **a** All figures are the percentage ranges of episodes reported.
- **b** Rounded to nearest whole percentage.
- **c** HACEK = Haemophilus sp., Aggregatibacter actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, Kingella kingae.
- **d** Includes a variety of single isolates of species not represented by above genera, including Neisseria sp., Pseudomonas, Legionella, Lactobacilli.

Compiled from references [1–4,8,9,15,27–31].

Enterococci rank third in frequency of isolation for most series, including healthcare-associated cases and those among patients on hemodialysis. Among the non–viridans streptococci, pneumococci are still relatively uncommon causes of endocarditis (1% to 3% of all cases) [36]. The proportion of cases caused by β-hemolytic streptococci has not increased since 1980; infections with group B and group G are seen most frequently [33,37,38]. Patients with these infections usually have underlying valvular disease (including prosthetic valves) [39], numerous predisposing factors, most notably diabetes mellitus, and acute onset of their infection [33,37,38]. The organism formerly called *Streptococcus bovis*, a non-enterococcal group D streptococcus, belongs to a larger group including *Streptococcus gallolyticus*, based upon DNA–DNA reassocation studies [39]. Some of the newly described species and subspecies (e.g., *S. galloityicus* subsp. *pasteurianus*) are more frequently associated with meningitis, while *S. galloityicus*, subsp. *gallolyticus* is associated with endocarditis and with benign and malignant disorders of the gastrointestinal tract. In some series, this organism group has been increasing in frequency in Europe and South America [9], particularly among the elderly and among patients with chronic liver disease [4,40–42]. When this organism is isolated, the patient should be carefully evaluated for gastrointestinal tract malignancy, although it may occur months to years after the bacteremic episode [41]. In fact, colonoscopy during the admission for endocarditis found premalignant or malignant lesions in 49% of patients with this organism [43], which we will hereafter refer to as *Streptococcus gallolyticus* (bovis), consistent with the usage in the American Heart Association (AHA) guidelines on IE [44]. *S. aureus* has increased in frequency and accounts for more than 50% of cases in more recent series [1,2,6,9,17,18,20,26,28]. In several recent prospective studies, including data from the International Collaboration on Endocarditis-Prospective Cohort Study (ICE-PCS), patients with *S. aureus* endocarditis were more likely than patients with IE due to other pathogens to have a shorter duration of symptoms before diagnosis, to be hemodialysis dependent, and to have other serious
comorbidities such as diabetes mellitus or other chronic illnesses [9,10,45–48]. Patients with *S. aureus* IE were also more likely to have severe sepsis with persistent bacteremia, major neurologic events, systemic embolization, and death than patients with IE caused by other bacteria [46–48]. In these studies, patients with *S. aureus* IE frequently had healthcare-associated or nosocomial acquisition and were more likely to have MRSA infection than patients with community-acquired *S. aureus*. In the ICE-PCS series [41], a multivariate model identified the following patient characteristics associated with MRSA IE: persistent bacteremia, chronic immunosuppressive therapy, intravascular devices as sources, and diabetes mellitus. Overall, MRSA now accounts for 25% to 50% of the cases attributable to *S. aureus* [2,26,45–48]. Persistent bacteremia correlated with infection caused by MRSA, and risk of embolic phenomena was negatively associated with oxacillin resistance [45–48].

Coagulase-negative staphylococci (CoNS) are recognized pathogens on prosthetic valves and close to 8% of cases on native valves are now caused by these organisms [49]. The majority of the CoNS species recovered are *Staphylococcus epidermidis* [49]. *Staphylococcus lugdunensis* has emerged as a particularly aggressive pathogen that causes a destructive NVE, frequently following vasectomy or other procedures involving breaks in the skin in the perineal area [50]. In spite of universal susceptibility to β-lactams and other agents, mortality attributable to this pathogen is high, possibly related to the large vegetations frequently seen with this organism, leading to valvular dehiscence, abscess formation, and systemic embolization [50].

Before 1980, endocarditis caused by Gram-negative organisms comprised less than 3% of cases. Recent series report that Gram-negative organisms now account for 4% to 10% of all NVE [3,6,16,51], but these rates vary by geographic location, whether the infection is community or healthcare associated and the type of Gram-negative pathogen involved. Within this subset is the HACEK group (*Haemophilus* sp., *Aggregatibacter* [previously *Actinobacillus*] actinomycetemcomitans, *Cardiobacterium hominis, Eikenella corroden*, *Kingella kingae*), which accounts for 2% to 5% of cases [8,9,27,51]. *A. actinomycetemcomitans* is the HACEK species most frequently involved in IE [51]. HACEK organisms are fastidious, nonmotile, slow-growing coccobacilli that require a mean of 3.3 days of incubation in automated blood culture systems for growth [51]. The HACEK organisms rarely cause endocarditis among patients without preexisting valvular disease or in the absence of
Non-HACEK Gram-negative endocarditis (Enterobacteriaceae and others) remains relatively rare and is seen primarily among debilitated patients with healthcare-associated infections related to medical devices or surgery [22,52,53], including PVE. The same epidemiologic features are associated with polymicrobial endocarditis, but at least in one series of polymicrobial endocarditis, Gram-negative bacilli were isolated less often than CoNS and enterococci [54]. However, 12 cases of endocarditis due to non-HACEK Gram-negative bacilli (eight on prosthetic valves and two in injection drug users) and only seven due to HACEK organisms were seen at one hospital in Paris during the years 2009 to 2014 [55].

Bartonella quintana [56,57], the agent of trench fever, Rochilimaea subsp. nov. elizabethae [58], and Bartonella henselae [58], the agent of cat scratch disease, were first reported as causes of endocarditis in 1993. In 1995, Bartonella quintana, the agent of trench fever, was identified in middle-aged, homeless male alcoholics without known underlying valvular disease [59]. Since then, multiple additional species of Bartonella have been discovered [60–62]. Seven species and subspecies, namely B. quintana, B. henselae (the agent of cat scratch disease), B. elizabethae, B. vinsonii spp. berkhoffii, B. vinsonii spp. arupensis, B. koehlerae, and B. alsatica have been implicated in cases of endocarditis [60,61]. Contact with animals is a frequent association, and ectoparasites such as scabies, lice, and fleas are proposed as possible vectors of disease [60–62]. The majority of patients with B. henselae endocarditis have a previous history of underlying valvular disease and report contact with cats [60–62]. Characteristically, patients with Bartonella endocarditis present with a subacute course and large vegetations [60–62]. Diagnosis based on serology and molecular methods has established Bartonella spp. as the cause of 1.1% of cases of IE in the United Kingdom, 3% in France, Germany, and Brazil [63,64], and 4.5% in Egypt [65]. The laboratory that has diagnosed the largest number of cases reports that the frequency of this organism appears to be stable over time [63]. Because of the fastidious nature of the organism and serologic cross-reactivity between antibodies to B. quintana and Chlamydia sp., it is likely that cases of Bartonella endocarditis constitute a proportion of cases previously diagnosed as culture negative or due to Chlamydia sp. [60–62].

In spite of improvements in blood culture and serologic techniques, negative blood cultures can occur in up to 31% of cases [1–3,7,66]. There are several reasons cited for negative blood cultures in IE: (a) prior antibiotic administration; (b) infection with fastidious, slow-growing organisms (e.g., Bartonella sp., fungi, Chlamydia and Coxiella spp.); (c) infection with nonbacterial organisms such as fungi; or (d) endocarditis of patients with an indwelling cardiac device such as a pacemaker.
Two surveys [66,67] of culture-negative cases in France over two decades used serologic studies and molecular methods to augment blood cultures in determining the etiology for more than 348 [66] and 740 [67] patients, respectively. In the initial study of definite cases of IE, among the 79% of patients with blood culture–negative disease in whom an etiologic agent was identified, *C. burnetii* and *Bartonella* sp. predominated, accounting for 76% of the total [66]. Other rare bacteria included *T. whipplei*, *Mycoplasma hominis*, various streptococci, and *Legionella pneumophila* [66]. Twenty-one percent did not have an etiology determined, of whom 79% had received prior administration of antibiotics [66]. In the more recent prospective series, both definite and possible cases were included and an etiologic diagnosis was determined for 64.6%. The same group of organisms predominated [67].

IE among injection drug users has increased in the new millennium and *S. aureus* is by far the most common cause [68,69]. Enterococci, enteric Gram-negative bacilli, *Pseudomonas, Candida*, and other yeasts are also important [6,9,68]. Polymicrobial endocarditis is more common among injection drug users than in non-injection drug users in most series [6,9,19], but in a series from Spain, only one out of 60 cases of polymicrobial endocarditis was in an injection drug user [54].

The common causes of early-onset PVE are CoNS (mostly *S. epidermidis*), *S. aureus*, enterococci, diphtheroids, Gram–negative bacilli, and fungi. In 11 (44%) of 25 cases, enterococci caused endocarditis with onset <12 months after transcatheter aortic valve implantation (TAVI) in a review of the literature [70] and 21% of all cases of endocarditis in a multicenter registry of 7944 patients who underwent this procedure [71]. The incidence of endocarditis in the first year after TAVI appears similar to that after surgical valve replacement, 0.50% [71]. Among the fungi, *Candida* sp. are the most common cause of PVE and have emerged as causes of both early- and late-onset disease, especially among patients with healthcare-associated infection [72]. However, late-onset disease is still caused mainly by organisms such as CoNS and streptococci, although *S. aureus* accounts for about 11% of cases [9,19,73,74]. This difference is thought to be explained by intraoperative or early postoperative contamination of the prosthesis with resistant hospital flora in early PVE. Late cases represent either smoldering infections with relatively avirulent organisms seeded at the original surgery or subsequent transient bacteremias, such as those that induce endocarditis on native valves [74].

“Surgery during initial hospitalization independently of the completion of a full therapeutic course of antibiotics is indicated in patients with left-sided IE caused by *S. aureus*, fungal, or other highly resistant microorganisms” (http://www.jtcvs.org/article/S0022-5223(17)30116-2/pdf).
The laboratory model of endocarditis is a rabbit in which a catheter passed through a valve produces mild trauma with the elaboration of a fibrin–platelet thrombus. Subsequent injection of bacteria either through the catheter or at a distant vascular site leads to infection of the traumatized valve [75]. It appears that the fibrin–platelet thrombus allows for avid binding of the bacteria [6]. Adherent bacteria induce blood monocytes to produce cytokines that contribute to further enlargement of the vegetation [76]. As the vegetation matures, the bacteria become fully enveloped, which allows for persistence by avoiding host defenses.

This model conforms to the propensity of damaged human valves toward endocarditis. Transient bacteremia with mouth flora, predominantly viridans streptococci, during chewing, toothbrushing, and the like, explains the pattern observed with subacute bacterial endocarditis [6]. More virulent organisms such as S. aureus seem to be able to invade even normal hearts. There are several factors expressed by this pathogen that make it more virulent. In addition to surface fibronectin-binding proteins that facilitate adherence, S. aureus produces exoenzymes and exotoxins that are controlled by global regulators, such as accessory gene regulator (agr) and staphylococcal accessory regulator (sar), the expression of which permits tissue invasion and destruction [6]. Intravenous drug users combine the injection of contaminated materials with particulate and often irritant matter, probably accounting for the frequency of endocarditis in this setting and the propensity for right heart involvement [68,77,78]. The use of intravascular central lines reaching near the tricuspid valve or even crossing tricuspid and pulmonic valves reproduces the rabbit model of endocarditis in humans. The introduction of bacteria through these lines causes the specter of iatrogenic endocarditis.

Once the fibrin–platelet thrombus has become infected, the pathologic process is the enlargement of this mass into a vegetation and invasion of tissue by the infection with eventual disruption. In addition to the mass of the vegetation, there are perforations or total erosions of valve cusps, rupture of chordae tendineae, fistulas from the sinus of Valsalva to atrium or pericardium, and burrowing myocardial abscesses.

Depending on the valve involved, the physiologic consequences may be predicted. Rarely, a vegetation will be so large as to function as an occlusive or stenotic lesion [78]. More often, the tissue destruction process predominates and valvular incompetence results. New regurgitant murmurs of mitral, tricuspid, or aortic origin may acutely
stress the heart with resultant congestive failure. Aortic valve disease carries the worst prognosis [78] for several reasons: (a) the heart tolerates acute aortic insufficiency least well; (b) pericardial tamponade or massive left-to-right shunt may develop if a sinus of Valsalva aneurysm erodes into the pericardium or right atrium, respectively; (c) heart block may occur if a myocardial abscess invades the conducting system; and (d) aortic valve ring vegetations are most likely to be flipped into the coronary arteries, infarcting already overworked muscle. These catastrophes are all even more likely in the presence of a prosthetic aortic valve, in which case the infection has its seat at the annulus. Tricuspid valve endocarditis is the most benign. Even total tricuspid insufficiency can be tolerated for a time, and acute right-sided heart failure is not as life threatening as is the pulmonary edema of left-sided failure.

The vegetations themselves may break off in whole or part as emboli to the brain, viscera (spleen and kidney are particularly common targets), coronary arteries, and notably in fungal endocarditis, large arteries of the extremities. Septic emboli to the lungs can result in pulmonary infiltrates, often nodular and sometimes cavitating. Emboli to other organs produce infarction, which is usually bland, although splenic abscess, brain abscess, and even purulent meningitis may occur in staphylococcal endocarditis. The most common cerebral lesion, however, is embolic infarct with the clinical appearance of a stroke [78,79]. The smaller vascular lesions of endocarditis may be of an immunologic, vasculitic nature or truly embolic and suppurative in character. Emboli to the vasa vasorum or vasculitis of the arteries lead to mycotic aneurysms of both cerebral and peripheral vessels. The cerebral aneurysms are generally asymptomatic until they rupture and present as subarachnoid or intracerebral hemorrhage. Peripheral mycotic aneurysms may come to attention because of their obvious enlargement, pulsation, and frequent overlying inflammation. Other phenomena that fall into this category are the cutaneous stigmata of endocarditis—Osler’s nodes, Janeway lesions, splinter hemorrhages, and petechiae—as well as the frequent renal involvement. Kidney pathology may take several forms: localized renal infarcts, vasculitic glomerulonephritis, acute diffuse glomerulonephritis thought to represent immune complex disease, renal cortical necrosis, and interstitial nephritis likely related to antibiotic administration [78].
Endocarditis is diagnosed on the basis of signs and symptoms that reflect the pathology: fever, embolic phenomena, and evidence of valvular dysfunction. A continuous bacteremia is characteristic and, indeed, highly suggestive of endovascular infection, although the entity of culture-negative endocarditis also exists. The frequency of various findings in IE is shown in Table 78.2 [1,3,4,9,15,19,28].

Criteria

Proof of the diagnosis, in terms of histopathologic confirmation of vegetation with infecting organisms on the affected valve, may be obtained only in cases requiring cardiac surgery or, in the event of death, with autopsy. Clinical criteria for the diagnosis sufficiently stringent to allow for analysis of case characteristics, epidemiology, and the outcome of therapy have been devised and revised over the years with the latest version known as the Duke criteria [27]. The Duke criteria incorporate echocardiographic findings in addition to giving heavy weight to clinical circumstances such as the type of organisms recovered from blood and injection drug use as a predisposing factor. Major and minor criteria analogous to the Jones criteria for diagnosis of rheumatic fever are summarized in Table 78.3. A definite diagnosis requires the presence of two major criteria, one major and three minor criteria, or five minor criteria. The diagnosis is rejected if a firm alternate diagnosis adequately explains the clinical findings, they resolve with less than 4 days of antibiotic therapy, or histopathologic evidence is lacking at autopsy or surgery performed after no more than 4 days of antibiotic therapy. All other clinically suspect cases meriting more than 4 days of antibiotic treatment are classified as possible [27].

Evidence of endocardial involvement

Positive echocardiogram for IE (TEE recommended in patients with prosthetic valves, rated at least “possible IE” by clinical criteria, or complicated IE [paravalvular abscess]; TTE as first test in other patients), defined as:

A. Oscillating intracardiac mass on valve or supporting structures, or in the path of regurgitant jets, or on implanted material, in the absence of an alternative anatomic explanation, or

B. Abscess, or

C. New partial dehiscence of prosthetic valve, or new valvular regurgitation (increase or change in preexisting murmur not sufficient)

Minor criteria

1. Predisposition: predisposing heart condition or injection drug use

2. Fever: >38.0°C (100.4°F)

3. Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions

4. Immunologic phenomena: glomerulonephritis, Osler’s nodes, Roth spots, rheumatoid factor

5. Microbiologic evidence: positive blood culture but not meeting major criterion as noted previously or serologic

acquired enterococci in the absence of a primary focus, or

Persistently positive blood culture, defined as recovery of a microorganism consistent with infective endocarditis from

A. Blood cultures drawn more than 12 h apart, or

B. All of three or a majority of four or more separate blood cultures, with first and last drawn at least 1 h apart

C. Single positive blood culture for Coxiella burnetii or anti-phase 1 IgG antibody titer ≥ 1:800
A definite diagnosis requires the presence of two major criteria, one major and three minor criteria, or five minor criteria. A possible diagnosis requires one major and one minor criterion, or three minor criteria.

*Excluding single positive blood cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis.

HACEK, Haemophilus sp., Aggregatibacter actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, Kingella kingae; IE, infective endocarditis; TEE, transesophageal echocardiography.

Several studies have demonstrated very good sensitivity and excellent specificity (92% to 99%) for the Duke criteria [80–82]. Moreover, these criteria have been evaluated for the diagnosis of IE in children [83] and the elderly [84], as well as in patients with PVE [85]. Several criticisms and proposed modifications have followed these rigorous studies. The inability of the Duke criteria to reject cases that receive more than 4 days of antibiotic therapy may lead to occasional overdiagnosis of endocarditis [86]. Modifications to the major and minor criteria, including serologic evidence of *Coxiella burnetii* (the agent of Q fever) infection and the category of “possible” endocarditis, requiring one major and one minor criterion or three minor criteria, as proposed by Li [87], are now recognized, as listed in Table 78.3.

**History**

The most frequent symptoms reported by patients with endocarditis are fever and malaise, but some present with acute musculoskeletal symptoms, most frequently lower back pain or polyarthralgia [88], and others, because of an embolus, without complaining of or even noticing fever [89]. A common feature of endocarditis is loss of appetite, and its return may be the first clinical sign of response to treatment. Any febrile illness of a patient with known valvular heart disease must bring to mind the question of endocarditis, as should fever in an injection drug user, especially with pleuritic pain. Other clinical scenarios in which endocarditis should be strongly considered include fever and back pain, stroke (particularly with fever or in a young person), acute unexplained renal failure, persistent bacteremia, and bacteremia with a suspect
organism (especially *S. aureus* or enterococcus) and no source. Similarly, a history of recent dental cleaning or extraction or genitourinary manipulation may indicate an opportunity for bacteremia and seeding of the valve and should be sought, as should suggestions of injection drug abuse. The history of appropriate antibiotic prophylaxis for these procedures is not sufficient to exclude the possibility of endocarditis, because failures occasionally occur with currently recommended regimens.

It is important to establish the duration and tempo of the illness by history. Abrupt onset of symptoms, shaking chills, and body temperature greater than 38.9°C (102°F) strongly suggest acute endocarditis. Subacute bacterial endocarditis, in contrast, is characterized by a vague illness occurring over a period of several weeks or months.

**Physical Examination**

In contrast to the vagueness of the symptoms of endocarditis, many findings on physical examination are characteristic. Most pertinent to the diagnosis are cardiac murmurs and mucocutaneous embolic phenomena. Any heart murmur is compatible with a diagnosis of endocarditis because it is evidence of the turbulent flow that provides the proper nidus for infection. The fact that a murmur has been documented for a long time in no way excludes the possibility of active endocarditis. Changing murmurs, particularly new regurgitant murmurs, are much less commonly observed but are highly significant with respect to both certainty of the diagnosis and functional consequences. Thus, patients must be examined both supine and sitting up leaning forward so that an aortic regurgitant murmur is not missed. Careful listening on both sides of the sternum during inspiration is important to detect tricuspid insufficiency. Signs of congestive heart failure are not early findings in endocarditis, but must be watched for, because the onset of failure signals a need to consider cardiac surgical intervention.

The most commonly observed mucocutaneous lesions of endocarditis are petechiae. They most often appear on the plantar surface of the toes and fingertips, as well as the conjunctival and buccal mucosa (see Fig. 78.1B). They may be larger and more irregular in outline than conventional petechiae and sometimes have a white or even pustular center. Conjunctival petechiae commonly occur in patients on cardiopulmonary bypass [90], so it is necessary to record their presence or absence on first encounter with a patient after cardiac surgery and to
interpret only those that develop under observation. The same necessity applies to subungual splinter hemorrhages, which are so commonly a result of trauma that many patients will have one or two on admission; only those which appear subsequently, while the patient is at rest in the hospital, have diagnostic usefulness [91].

**FIGURE 78.1** Embolic phenomena in a single patient with *Staphylococcus aureus* endocarditis. A: Conjunctival petechiae. B: Petechiae on fingertips; note irregular margins. (Courtesy of Biomedical Media, University of Massachusetts Medical Center.) C: Fundus hemorrhage with white center, known as Roth spot. (Courtesy of Harry Kachadoorian, Ophthalmology Clinic, University of Massachusetts Medical Center.)

Osler’s nodes and Janeway lesions favor the plantar and palmar surfaces but are uncommon in recent series of endocarditis. Osler’s node is a painful, tender, bluish-purple nodular lesion located on the pads of the fingers or toes. The Janeway lesion is a painless, pink, nontender macular lesion that is located commonly on the palms or soles [91,92].

Fundoscopic examination may also show evidence of endocarditis. Showering of emboli often occurs, as in the patient whose findings are illustrated in Figure 78.1. The fingertip, subungual, conjunctival, and retinal lesions all developed the day after admission for acute renal failure, subsequently found to be due to *S. aureus* endocarditis.
Splenomegaly is found in nearly half of the patients with subacute bacterial endocarditis and in very few of those with acute disease.

**Laboratory Tests**

The key to the diagnosis of endocarditis is blood cultures. The current practice of early initiation of antimicrobial therapy for acutely ill patients has led to the recommendation that at least three separate blood cultures be drawn from separate sites with a minimum of 1 hour between the first and the last [44]. Strict aseptic technique and optimal skin preparation should be used when collecting blood cultures and the blood cultures should be obtained prior to administration of antibiotics [44]. In adults, 20 to 30 mL of blood per culture is optimal [44]. In cases that appear to be culture negative [66,67,93], the advice of a clinical microbiologist should be sought regarding the need for special media, such as those adequate for the propagation of *Brucella* sp., *Bartonella* organisms, or other nonculture-based tests such as serology and molecular methods (see later). Prolonging the incubation of standard blood culture bottles beyond 7 days has not been demonstrated to be necessary for successful recovery of HACEK organisms, nor does it significantly improve diagnostic yield of other fastidious pathogens [93–95].

Diphtheroids and CoNS should not be disregarded as skin contaminants if isolated repeatedly; they are well established causes of endocarditis. A particularly troublesome problem is the recovery of CoNS of different colony types or susceptibility patterns from different blood cultures. This is not necessarily evidence for multiple contaminated cultures because the pattern can be observed in true coagulase-negative staphylococcal endocarditis.

Fungal endocarditis has become more frequent. Fungi most commonly isolated include *Candida albicans*, followed by *Candida parapsilosis*, then other non-albicans species of *Candida* [96], *Aspergillus* sp., and *Histoplasma* sp. [72,97]. In one review, emerging fungi accounted for 25% of cases [97]. Among patients with fungal endocarditis, the overall frequency of positive blood cultures is 54% [97]. Among cases of endocarditis caused by *Candida* sp., the percentage of positive blood cultures may be as high as 83% to 95% if appropriate methods are used [93].

Current commercially available routine manual and automated blood culture systems are usually able to recover yeasts within 5 to 7 days of incubation. The best chances for recovery of filamentous fungi such as *Aspergillus* or *Histoplasma* require the use of the lysis centrifugation
method (Isolator, Wampole Laboratories, Cranbury, NJ) [93].

Premortem microbiologic diagnosis may often be made by culture and special histologic stains of large arterial emboli or cardiac vegetations [66,97].

Noncultivatable or difficult to cultivate organisms may be detected by serologic or molecular studies. Such organisms include *C. burnetii*, the agent of Q fever endocarditis, *Chlamydia* sp., *Bartonella* sp., and some fungi [60–62,66,67,97,98]. Timely inclusion of serologic studies, particularly in environments where Q fever, *Brucella*, and *Bartonella* sp. are prevalent, can enhance the definitive diagnosis of cases of endocarditis as demonstrated in the studies by Raoult et al. [67,99].

Molecular techniques such as polymerase chain reaction and sequence analysis of the amplified DNA have been applied to blood cultures, whole (EDTA) blood, and to valvular tissue removed at the time of surgery [63,67,100,101]. Several studies have demonstrated the utility of these methods in assessing patients with high pretest probability of endocarditis but who have negative blood cultures by standard methods. Many of these studies are well summarized in the review by Syed et al. [100]. Advantages include high sensitivity, rapid results, and accurate identification. Limitations include potential for contamination and lack of an organism to test for antimicrobial susceptibility [67,100,101].

Other Diagnostic Tests

The electrocardiogram (ECG) is the simplest test for evaluation of perivalvular extension of infection in endocarditis [102]. Persistent (2 to 3 days) prolongation of the PR interval in the absence of digitalis toxicity, new persistent bundle-branch block, or complete heart block is quite specific for predicting extension into myocardial or aortic root tissue and the subsequent need for surgery [102]. However, the absence of PR prolongation does not rule out perivalvular extension.

Echocardiography plays an essential role in the diagnosis and management of IE and should be performed in all cases of suspected endocarditis [44,103,104]. Current roles for echocardiography include (a) diagnosis of IE by demonstration of vegetations, (b) characterization of underlying valvular disease, (c) clarification of the destructive nature of endocarditis, (d) assessment of the persistently febrile patient for evidence of perivalvular extension of infection, and (e) assessment of valvular function for PVE.

Studies performed in the period between 1988 and 1998 demonstrated that transthoracic two-dimensional (2D) echocardiography (TTE) has an overall sensitivity of vegetation detection of 50%, with a range of 14% to 78% in published series [105–107]. Sensitivity is affected by vegetation size, with 25% of vegetations less than 5 mm and 70% between 6 and 10
mm detected [108]. Obesity, chronic lung disease, and thoracic deformity may preclude obtaining the high-quality images needed to detect vegetations in as many as 30% of patients [108,109]. Equivocal results due to thickening or myxomatous degeneration of native valves and artifact from prosthetic valves are problems with TTE [106,109]. Diagnostic yield is also influenced by experience and skill of the person performing the procedure and the pretest probability of endocarditis. TTE has very limited ability to detect valve perforations and abscess extension, especially on prosthetic heart valves. Technologic advances such as harmonic imaging and digital processing and storage have improved TTE image quality [100,110]. At least one report describes improved sensitivity to more than 80% using contemporary TTE [110]. Transesophageal echocardiography (TEE) is a significant advance for the evaluation of the patient with IE [100,106,111]. Unlike TTE, TEE has a high negative predictive value for patients with suspect NVE (86% to 97%) [100,106,111]. Despite the somewhat invasive nature of TEE, the procedure is quite safe when performed by a skilled physician, with interruption of the procedure or complications occurring less than 1% of the time [112]. Relative contraindications include esophageal diseases, severe atlantoaxial joint disease, prior irradiation to the chest, and perforated viscus [113].

Image quality of the TEE benefits from the high-resolution transducer and unobstructed view of cardiac structures [102,106–109]. The TEE is much more sensitive than TTE for the detection of valvular vegetations; sensitivity with current biplane TEE is 90%, with vegetations as small as 1 mm being seen [112,114–116]. Early studies on 3D TEE demonstrate the potential of this technology to enhance localization of vegetations [117]. Like the situation with 3D TTE, however, large series demonstrating superiority are lacking.

TEE is also superior to TTE for detection of perivalvular abscess, with approximately 87% sensitivity [105,114]. TEE appears to be the optimal tool to detect vegetations on prosthetic valves and to assess valve dysfunction. Likewise, TEE is superior to TTE for detecting infections of pacemaker leads [109,116–119]. TEE also appears superior to TTE in the intraoperative assessment of cardiac structure and hemodynamics [116,118].

The AHA guidelines [44] prefer TEE for all patients with suspected endocarditis, but do accept that it may be omitted when TTE is diagnostic for endocarditis and the likelihood of complications is felt to be low. TEE is definitely indicated for the diagnosis of endocarditis in the presence of a prosthetic valve and when clinical suspicion of endocarditis is high but TTE is negative [44,103,104]. Whenever TEE is positive, TTE views of the areas with abnormal findings should be obtained for comparison during follow-up [44]. The European Society of Cardiology (ESC) practice
guidelines [103] similarly recommend TEE for all cases except those for whom good quality TTE images and unequivocal findings demonstrate isolated right-sided endocarditis. All of the guidelines agree that echocardiography should be repeated when the initial imaging is negative and clinical suspicion remains high: TTE or TEE in 3 to 5 days [103], TEE in 5 to 7 days [44], TTE or TEE in 7 to 10 days [104]. TEE should also be obtained when the TTE is positive but the patient’s clinical course suggests the development of cardiac complications [44,103,104].

Investigators have attempted to determine cost-effective uses of echocardiography for patients with suspected endocarditis [120,121]. Some advocate that if the pretest probability is high (ranging from 4% to 60%), it is more cost-effective to proceed directly to TEE as the first and only study [120]. For determination of duration of therapy for catheter-associated S. aureus bacteremia (SAB), TEE is probably most cost-effective when used to stratify patients to short (2 weeks) or long (4 weeks) course therapy, when long-course therapy would have otherwise been chosen for an at-risk, native valve population without immunocompromise [121].

The prognostic implications of vegetations identified by echocardiographic studies remain controversial. Some recent studies have indicated an increased risk of embolization in patients with vegetations greater than or equal to 10 mm in size, particularly in patients with mitral valve disease [122,123]. Still others have found that the predictive value of size for embolization depended on the organism and the mobility of the vegetation [122–124]. Most investigators agree that the presence of a vegetation alone is not an independent indication for valve replacement [122,123].

Although emboli may occur in as many as 16% of patients with Duke definite endocarditis who do not have vegetations on echocardiography [125], vegetations greater than or equal to 10 mm in size are associated with an increased risk of embolization [122,123,125]. Mitral location, causative organism, and the mobility of the vegetation also contribute to embolic risk, and echocardiography may be useful for stratifying patients to high-risk subgroups where early surgery should be considered [122–125].

TEE is inconclusive in 10% to 20% of patients with suspected IE [126]. Adjunctive imaging modalities such as multislice computed tomography (CT) are complementary to TEE and may improve diagnosis rates in difficult-to-detect cases. Further, CT may have advantages in detecting perivalvular diseases associated with IE such as root abscess,
pseudoaneurysm, or fistula, as well as in the evaluation of patients with extensive valvular calcifications. CT is inferior to TEE in detecting small vegetations and valve perforations, and its use is limited among patients with poor renal function or who cannot tolerate iodinated contrast [127]. Molecular imaging modalities such as $^{18}$F-fluorodeoxyglucose ($^{18}$F-FDG) positron emission tomography or single photon emission computed tomography have also shown promise in confirming the diagnosis in patients with suspected IE by Duke criteria, nearly doubling the diagnostic sensitivity for IE compared to using the Duke criteria alone [127]. However, these molecular modalities are time-consuming, expensive, and may not be able to differentiate IE from inflammatory changes due to surgery or other conditions such as vasculitis [126]. Neither U.S. nor European guidelines currently recommend the routine use of alternative imaging modalities such as CT or nuclear imaging in the diagnosis of IE [44,103], but their adjunctive use alongside traditional cardiac imaging modalities may prove useful in the evaluation of patients with perivalvular extension of disease or with inconclusive echocardiographic findings.
DIFFERENTIAL DIAGNOSIS

By far, the most common difficulty confronting the present-day practitioner is deciding which episodes of bacteremia represent endocarditis. The question becomes particularly acute for patients with intravascular foreign bodies, such as pacemakers, valves, and patches, and when the organism is *S. aureus*. The approach to this problem must take into account the propensity for the foreign body to become infected, the propensity of the organism to cause endocarditis, and the duration of bacteremia. Because sustained bacteremia characterizes infection of endovascular sites, the longer the bacteremia lasts, the greater the concern for an endothelial origin. In addition, even if the origin is distant and known, the longer the organisms circulate, the greater is the risk that they have settled out and seeded the intravascular foreign body secondarily.

Prosthetic valves, both mechanical and of biologic origin, have a very high risk of becoming infected, whereas permanent pacemakers (PPMs), once endothelialized, appear to carry a relatively low risk. Infection usually occurs at the skin–catheter junction and thus is most likely to invade the circulation when the vessel is in close proximity to the skin wound. However, for patients with a PPM, sustained bacteremia without an obvious focus implies infection of the pacemaker electrode, the tricuspid valve, or fibrotic endocardial regions in contact with the electrode tip [128].

Enteric Gram-negative bacilli are among the most common blood culture isolates at most hospitals but are less common as a cause of endocarditis (see Table 78.1). Notable exceptions to this characterization of enteric Gram-negative bacilli are salmonellae, particularly *S. typhimurium* and *S. choleraesuis*, which seem to have an affinity for damaged vascular endothelium and have infected aortic aneurysms as well as cardiac devices [129]. AIDS patients older than 50 years who develop salmonella bacteremia in the setting of predisposing valvular disease appear to be at particular risk of endocarditis [53,130].

Nosocomial bacteremia with Gram-negative bacilli has been shown to constitute a risk for development of PVE. Fang et al. [131] found that 26% of new cases of PVE occurred among patients who developed nosocomial Gram-negative bacteremia, in most cases from an identifiable portal of entry. Thus, patients with Gram-negative bacteremia in the setting of a prosthetic valve should receive antibiotic therapy adequate for possible endocarditis.

SAB always raises the question of whether treatment as endocarditis is warranted. A classical study reported that 64% of all bacteremias with *S.
*aureus* from 1940 to 1954 represented endocarditis, proved by autopsy in 38% of cases [132]. A subsequent report from the same center defined 16% of 134 patients with SAB from 1975 to 1977 as having definite or probable endocarditis [133]. These and other studies have amply demonstrated the ability of *S. aureus* to produce endocarditis on a valve previously presumed normal and have shown that established endocarditis may be found at postmortem examination in patients in whom no murmur was ever heard during their lifetime [48,132]. The changing demographics of staphylococcal endocarditis have been discussed in detail in the “Etiology” section of this chapter.

The absence of a primary focus appears to be a powerful predictor of endocarditis from community-acquired staphylococcal bacteremia [48,134]. Injection drug users are also at high risk of endocarditis and metastatic abscesses, and SAB should be treated in a fashion appropriate to endocarditis whenever it occurs in this group.

IE has been shown to be clinically occult in a high proportion of patients with staphylococcal bacteremia [135]. TEE has been valuable for identifying which patients have endocarditis in the setting of staphylococcal bacteremia [45,121,135]. One study examined the use of a scrupulous definition of negative TTE plus clinical criteria (absence of any of the following high-risk features: community-acquired *S. aureus* bacteremia [SAB], prosthetic valves or valve repair materials, intracardiac devices, history of prior endocarditis, or injection drug use) among patients with SAB [136]. A TTE was called negative only if it was not suboptimal or indeterminate in any way and had no abnormality, even if that abnormality did not fulfill any criteria for endocarditis, strictures that excluded 22% of the TTEs performed. In their validation cohort of 268 patients with SAB and a 14.2% prevalence of endocarditis, these rules would have missed only one case of IE, a negative predictive value of 99% [136].

Several studies support the use of a 2-week course of antibiotic therapy for catheter-associated SAB in patients at low risk of endocarditis. This would include patients without valvular heart disease (or prosthetic valves) and in whom the catheter has been removed promptly, subsequent blood cultures are negative, defervescence occurred within 72 hours, and TEE is normal [121,137,138]. Failures may still occur in up to 16% of cases assessed as low risk using these criteria [138]; recurrences are reported in 5% to 24% of patients with catheter-associated SAB, usually within 10 weeks of discontinuing therapy [139,140]. Clearly, patients who have prolonged fever or bacteremia after catheter removal
should receive the longer course of antibiotic therapy because of the high mortality from catheter-associated *S. aureus* endocarditis \[46,139,140]\. All patients with SAB, whether treated with short or longer courses of therapy, should be followed closely for at least 3 months following treatment, preferably by an infectious diseases specialist \[141]\.

The overall mortality rate for staphylococcal endocarditis in one multicenter study ranged from 16.7\% to 23.7\% \[46\]. Overall mortality rates of 36\% to 48\% have been reported during the last decade \[142]\. In contrast, human immunodeficiency virus (HIV)–seronegative parenteral drug users with this disease have a 2\% to 4\% mortality rate, although considerable morbidity, including congestive heart failure, occurs in 23\% \[142]\. The more favorable outcome of injecting drug users is generally attributed to their younger age and absence of underlying systemic illness, as well as the location of their valve involvement (right-sided valvular disease). In the HIV-seropositive injection drug user, mortality is related to the degree of immunosuppression \[143]\. In one study, for patients with CD4 counts of 200 or more, there was no difference in mortality between HIV-positive and HIV-negative individuals and mortality was directly related to the valve involved \[142]\.

The epidemiology of enterococcal bacteremia has also changed \[144]\. Enterococci have emerged as major causes of healthcare-associated infections and in so doing have become increasingly resistant to antimicrobial agents, most importantly the penicillins, aminoglycosides, and glycopeptides \[17,144–146]\. Frequently, the enterococcus occurs in polymicrobial bacteremic infections along with enteric Gram-negative bacilli \[146]\, but it may also accompany other Gram-positive organisms, particularly CoNS \[54]\. Mortality attributed to enterococcal bacteremia is high, ranging from 13\% to 42\%, and seems to correlate directly with the severity of underlying illness as well as with antimicrobial resistance \[146,147]\. Higher mortality rates are seen among patients infected with strains that have high-level aminoglycoside resistance and resistance to vancomycin \[146–148]\.

Two case series of patients with enterococcal bacteremia examined the risk factors for development of endocarditis \[144,145]\. These studies refute previous reports that nosocomial bacteremia and polymicrobial infections with enterococci are rarely associated with endocarditis. In both studies, *E. faecalis* was the predominant enterococcal species. Approximately 60\% of the patients had nosocomial infections and polymicrobial bacteremia varied from 17\% to 37\%. Factors that were significantly associated with endocarditis included three or more positive blood cultures, the presence of a prosthetic valve, underlying valvular disease, and infection with *E. faecalis* \[144,145]\.
INFECTIONS OF CARDIOVASCULAR IMPLANTABLE ELECTRONIC DEVICES: PACEMAKERS, AUTOMATIC IMPLANTABLE CARDIOVERTER DEFIBRILLATORS, AND VENTRICULAR ASSIST DEVICES

Cardiovascular implantable electronic devices (CIEDs) are essential for the management of cardiac disease, and their use has increased significantly in the United States [149,150]. A recent population-based survey on the use of CIEDs reported that 70% of device recipients are elderly and many of these patients have multiple coexisting illnesses placing them at risk of CIED infections [151]. Despite improvements in the technology and greater ease of implantation, CIED infections appear to be increasing with the probability of infection being higher among patients with implantable cardioverter defibrillators (ICDs) than with PPMs [149,152,153]. Nearly 50% of patients in one series had undergone invasive procedures or hospitalization within the 6 months preceding their CIED infections [153].

Several recent studies have identified risk factors for PPM infection including long-term corticosteroid use, the presence of more than two pacing leads versus two leads, fever within 24 hours of implantation, early reinterventions, and the use of temporary pacing before the implantation [154,155]. Other patients at risk include those individuals with diabetes mellitus, renal dysfunction, heart failure, and oral anticoagulant use [149,153]. Studies that examined this outcome showed a lower risk of infection among patients given perioperative antimicrobial prophylaxis for the implantation procedure [149,154,155].

Infections of pacemakers can be divided into the following distinct syndromes:

Generator pocket infections, which tend to occur within 2 months of surgery and are usually caused by S. aureus.
Infections associated with the lead wire and electrode, which generally present months later and are more typically caused by CoNS.
Endocarditis, which usually follows contiguous spread of infection along the pacer system.
Inflammation at the generator pocket may be absent or detectable only at surgery in patients with the latter two syndromes [150].

Local erythema, erosion over the generator site, or drainage characterizes pocket infections, whereas electrode infections and endocarditis present more typically with sepsis and sustained bacteremia. Among cases of pacemaker endocarditis, TEE is a useful diagnostic tool for defining the pacemaker as the source of bacteremia by visualizing vegetations on the leads or the tricuspid valve, as well as the possibility of left-sided valvular involvement, myocardial abscess, and other cardiac complications [103,119,149,150,156].

Infections that involve pacemaker wires and electrodes are almost never cured with antibiotics alone, and the entire system should be removed [103,149,156]. This usually can be accomplished in a one-stage procedure in which the old system is removed and the new system placed at a site remote from the infection (usually the contralateral side), followed by a course of antibiotics [149]. However, temporary pacing is not recommended and new device placement should be delayed until blood cultures have been negative for at least 72 hours in cases of bacteremia, and only if reevaluation of the indications determines that it is still required [103,149]. The optimal duration of antimicrobial therapy depends upon the extent of infection and whether bacteremia is present. Short-course therapy following extraction may be possible for infections confined to the pacer pocket in the absence of bacteremia, whereas much longer duration of treatment is essential in patients with bacteremia. Patients with *S. aureus* bacteremia and no obvious source should have all hardware removed. Guidelines for management are discussed in detail elsewhere [103,149].

Removal of the old system may not always be easy to accomplish. Sometimes defective or infected electrodes become firmly enclosed by fibrous tissue and are adherent to the vessel endothelium, precluding easy extraction through the venous system. Removal of a retained wire using traction devices has been successful in some instances, but serious complications such as avulsion of the tricuspid valve and creation of atrioventricular fistulae have been reported [156]. Specialized tools have been developed to remove leads from fibrotic tissue. The newest technologies are laser sheath devices. A multicenter study reviewed the experience with laser sheath extraction in the United States where 1,684 patients (2,561 leads) were treated with a laser sheath [157]. Complete success, defined as removal of all lead material from the vasculature, was seen in 90% of the patients. The most predictive factor
for failure to remove a lead by this procedure was lead implant duration of more than 10 years. Cardiopulmonary bypass surgery with dissection of the electrode may be required for patients who can tolerate surgery when percutaneous approaches are not successful or intracardiac complications, including valvular involvement, are present [103,149,156].

Infection is one of the most serious complications of automatic implantable cardioverter defibrillators (AICDs). Infection rates of older AICDs, in which one of the electrodes is a surgically implanted epicardial patch, range from 1% to 7% [158]. Early infections typically involve the generator pocket and are caused by *S. aureus* [158]. Late infections tend to involve the patch with resultant purulent pericarditis, usually caused by CoNS and corynebacteria [159]. There is now agreement that these infections, whether early or late, require removal of the entire system [149,159]. Radical debridement of the pericardium is necessary if infection extends beyond the electrode patch capsule [159]. Prolonged antibiotic therapy (i.e., 6 weeks) follows these procedures. Reimplantation of the generator following disinfection and appropriate gas sterilization using new electrodes and wires after the patient has been on antibiotic therapy for 2 weeks has been successful [158] but is not recommended [149]. More recent AICDs use intracardiac defibrillating electrodes placed transvenously; management of infections involving these systems is similar to that of PPMs [149].

Ventricular assist devices have revolutionized the management of patients with end-stage cardiac pump failure. They may be used temporarily in patients who are expected to have recovery of natural heart function, as a “bridge” in the group who are awaiting cardiac transplantation, or as destination therapy in patients ineligible for transplantation. A ventricular assist device consists of an encased pumping chamber usually placed in a preperitoneal or intraabdominal position, a driveline tunneled to an exit point in the lower quadrant, and inflow and outflow conduits with unidirectional valves attached with a Dacron graft to the left ventricular apex and the ascending aorta, respectively, each of which locations has its own peculiarities and propensity to infection [160]. Incidence of infection following left ventricular assist device (LVAD) implantation ranges from 18% to 59% [160]. Infections range in severity from local driveline exit site infections to pocket (meaning the body cavity, either preperitoneal or intraabdominal, in which the device is placed) infection and bacteremia, for which determining whether the device is, in fact, seeded is the key question [161]. A series published in 2006 reported that most infections occurred between 2 weeks and 2 months of implantation [160], but a more recent report of infections in LVADs placed from 2005 to 2011 found endovascular infections occurred early (0.3 to 7.3 months, median 1.6 months) postimplantation, whereas “local” infections, predominantly
involving the driveline exit site, tended to occur later (3 to 19.8, median 7.1, months) [161].

The most serious of these infections is LVAD endocarditis, defined as infection of the LVAD surface or valves associated with persistent bacteremia or fungemia [160]. Clinical features include persistent fever, cachexia, septic cerebral embolization, and device failure [160–162]. Pathogens are typical nosocomial organisms: Gram-positive cocci, particularly staphylococci, are the most frequent etiologies, followed by Gram-negative bacilli including *Pseudomonas aeruginosa* and *Candida* sp. [160,161]. Mortality with LVAD endocarditis is high, approaching 50% in one series [162]. All-cause mortality was 43% at 2 years from the time of implantation in a series that included all LVAD-related infections; 47% of the 30 patients whose LVADs were intended as bridge to transplant actually received heart transplants [161]. A recent paper proposes an algorithm to guide workup and therapy of these infections; the authors stress that chronic suppressive antimicrobial therapy is indicated when the LVAD is believed to be seeded and recommend continuation of that therapy even if the device is explanted and replaced [161].
TREATMENT

Treatment of IE encompasses antimicrobial therapy, close clinical monitoring, and the decision as to whether and when surgical intervention should be undertaken. In a consecutive series of patients admitted to medical ICUs at a single hospital in France between 1993 and 2000, the in-hospital mortality rate was 45% (102 of 228) [163]. In an international collaborative study of NVE managed between 2000 and 2005 at 61 centers in 28 countries, the in-hospital mortality was 143 of 1,065 (13%) in patients with community-associated disease and 138 of 557 (25%) in patients with healthcare-associated infection [17]. Mortality for PVE is higher and ranges from 13% to 45% [164]. In the years since 2000, antimicrobial resistance has increased among the usual causative organisms, particularly staphylococci and enterococci, increasing the challenge of treating these infections.

Antimicrobial Therapy

Antimicrobials used to treat IE must provide bactericidal activity in the bloodstream, bathing the infected vegetation and heart valve, since neither possesses an intrinsic vascular supply, and bacteria within the vegetation may be shielded by the surrounding fibrin–platelet thrombus. Certain organisms also produce a slime around indwelling devices that provides a further barrier to antimicrobial penetration and alters killing conditions. In vitro and animal model systems can suggest potential approaches to therapy, but clinical outcomes are the final arbiter of whether a particular drug or combination of drugs has worked for the patient with endocarditis. There have been very few controlled clinical trials [165–168]. Rather, regimens have been evaluated by comparing cure rates to those expected. In the clearest case, “Bacteriologic cure rates ≥ 98% may be anticipated in patients who complete 4 weeks of therapy with parenteral penicillin or ceftriaxone for endocarditis caused by highly penicillin-susceptible viridans group streptococci or S. gallolyticus (bovis)” [44]. For other etiologies of IE, the expectation of successful therapy is less uniform. Extensive reviews of published data and the clinical wisdom of experts in the field provide the basis for the therapeutic recommendations of various guidelines ([44], United States; [103], Europe; [104], United Kingdom [see individual references for Web site addresses]).
In the following discussion, we review the major U.S. recommendations [44] but urge the reader to consult the most up-to-date version of them at the time of need and take care to note the specifics of the organism, valve type, and dosing recommendations.

**Streptococci**

For the highly penicillin-susceptible viridans group streptococci and S. *galloyticus (bovis)* with penicillin MIC ≤0.12 μg per mL, the dose of aqueous crystalline penicillin G is 12 to 18 million units IV given either continuously or divided into four to six daily doses, or ceftriaxone 2 g IV or IM given as a single daily dose. Duration of treatment is 4 weeks for NVE. A randomized controlled trial has shown that the addition of gentamicin, 3 mg per kg IV once daily, given in close temporal proximity to the dose of the cell-wall active agent (penicillin or ceftriaxone), can reduce the duration of treatment to 2 weeks for patients without cardiac complications or extracardiac sites of infection [165]. For prosthetic valve infections, 6-week therapy with the β-lactam is recommended, and gentamicin is optional [44]. Endocarditis due to group A β-hemolytic streptococcus (S. pyogenes or GAS) is treated similarly, with penicillin, ceftriaxone, or vancomycin (when the patient cannot tolerate β-lactams) for 4 to 6 weeks [44].

Note that the 2015 version of the U.S. guidelines [44] includes continuous infusion of penicillin among the recommended dosing schedules, and that one study has demonstrated significantly better outcomes (odds ratio for successful therapy 2.79, CI 1.43 to 5.62) for patients who received penicillin on a q4h schedule compared to those dosed at 6-hour intervals [169]. Ampicillin, 2 g IV every 4 hours, may be used in place of penicillin. Vancomycin is recommended for patients with endocarditis due to streptococci only if they are unable to tolerate penicillin or ceftriaxone. The vancomycin dose is 15 mg per kg IV every 12 hours, adjusted to yield trough levels of 10 to 15 μg per mL [44]. Desensitization to a β-lactam antibiotic, rather than use of vancomycin, should be strongly considered for patients with anaphylactic β-lactam allergies. These comments apply to all regimens using these drugs.

For strains of viridans group streptococci and S. *galloyticus (bovis)* with penicillin MIC greater than 0.12 but less than or equal to 0.5 μg per mL, the penicillin dose is higher (24 million units per day), 2-week therapy is not an option, and a single daily dose of gentamicin is recommended for the first 2 weeks of a 4-week course in NVE and for the entire 6-week course for prosthetic valve disease. Ceftriaxone may be used if the organism is susceptible, in which case gentamicin may be omitted from the treatment of native valve disease but should be given for the full course in PVE. If vancomycin must be used because the patient is
intolerant to β-lactams, gentamicin is not recommended [44]. Highly penicillin-resistant viridans group streptococci (penicillin MIC ≥ 0.5 μg per mL) may be treated with combination penicillin or ampicillin plus gentamicin (see regimen for enterococci, below), or if susceptible to ceftriaxone, with that drug plus gentamicin. If vancomycin is required, gentamicin is not given [44]. Patients with pneumococcal endocarditis may have concomitant meningitis (present in 40.8% of cases in a recent series [36]), in which case the β-lactam or vancomycin dose must be appropriate for the latter indication [44]. The European guidelines recommend use of ceftriaxone rather than penicillin or ampicillin in this circumstance (unless the susceptibility of the organism requires addition of vancomycin) [103]. Even in the absence of meningitis, high-dose penicillin or ceftriaxone should be used, and the addition of vancomycin and rifampin may be considered if the S. pneumoniae MIC is greater than 2 μg per mL [44]. Treatment duration is 4 weeks for native valve disease and 6 weeks for PVE [44]. For groups B, C, and G β-hemolytic streptococcal endocarditis, including the S. anginosus (milleri) group, recommended treatment is penicillin or ceftriaxone with the addition of gentamicin for at least the first 2 weeks of a 4- to 6-week course [44].

**Staphylococci**

Most centers must now use vancomycin as the initial therapy for suspected S. aureus infection, despite slower killing and inferior clinical response, due to the frequency of oxacillin resistance in both healthcare-associated and community-acquired strains. Empirc vancomycin should be changed to nafcillin or oxacillin, 2 g IV every 4 hours (or cefazolin, 2 g IV every 8 hours, for patients with non-anaphylactoid β-lactam hypersensitivity) when S. aureus is determined to be susceptible to oxacillin; desensitization to oxacillin or nafcillin should be strongly considered for patients with anaphylactic β-lactam allergies. Controlled trials have shown that the addition of gentamicin does not improve outcome in native valve S. aureus endocarditis [166–168]. Recent data also suggest that even short courses of low doses of gentamicin are associated with nephrotoxicity in patients with SAB and endocarditis, particularly in patients with any degree of baseline renal dysfunction, advanced age, or diabetes [170]. Gentamicin is no longer recommended for treatment of NVE due to S. aureus in any of the major guidelines [44,103,104]. However, gentamicin is recommended for the first 2 weeks of therapy of PVE caused by gentamicin-susceptible staphylococci. U.S. guidelines favor q8–12h gentamicin dosing [44], whereas the European recommendation is a single daily dose [103]; both recommend 3 mg/kg/d. If the organism is gentamicin resistant but susceptible to a fluoroquinolone, then addition of a fluoroquinolone to the β-lactam or
vancomycin can be considered for PVE. Rifampin has a special role in PVE because of its ability to sterilize devices (probably due to activity within the slime); the dose is 300 mg by mouth (preferred) or IV every 8 hours. Rifampin should be given for the entirety of the course, if the organism isolated is susceptible. The European guidelines recommend waiting 3 to 5 days before starting rifampin; this provides time to be sure the organism is susceptible, and may decrease the likelihood of selecting for rifampin resistance while the organism is still replicating rapidly. The usual duration of therapy for *S. aureus* endocarditis is 4 weeks for uncomplicated cases, 6 weeks for complicated cases, and 6 or more weeks for PVE, although a 2-week course of nafcillin or oxacillin can be used for selected cases of native valve *S. aureus* endocarditis limited to the right side of the heart.

For MRSA endocarditis, vancomycin is still the current first-line recommendation, but there is growing dissatisfaction with its efficacy. A review of multiple case series established that mortality and treatment failure are significantly more frequent among bloodstream infections caused by MRSA with vancomycin MICs ≥ 1.5 μg per mL which are considered vancomycin-susceptible using the current standard susceptibility cutoff. The European guidelines have responded to this by urging higher doses of vancomycin (aiming at trough levels >20 μg per mL) and recommending alternative agents, including daptomycin at a dose of ≥10 mg/kg/d along with a β-lactam or fosfomycin, or cotrimoxazole (trimethoprim-sulfamethoxazole) plus clindamycin for MRSA endocarditis. The U.S. guidelines discuss some of these options, as well as noting that none of the treatment failures in an early study of trimethoprim-sulfamethoxazole occurred in patients infected with MRSA ([44], referring to [171]). The difficulty with treating these strains may not be entirely due to their resistance to vancomycin: higher in-hospital mortality was also found among patients with endocarditis due to methicillin-susceptible *S. aureus* with vancomycin MICs ≥ 1.5 μg per mL, even though they were treated with a β-lactam.

Staphylococci with vancomycin MICs < 2 μg per mL are still generally treated with that agent. The addition of synergistic gentamicin is not thought to be more useful in this situation than for oxacillin-susceptible disease, and coadministration with vancomycin may increase toxicity. Addition of rifampin to vancomycin therapy is not recommended due to a lack of benefit on either survival or duration of bacteremia.

CoNS, best known for causing prosthetic valve and other device infections, should be assumed to be oxacillin resistant until proven
otherwise by rigorous testing (not available in all laboratories). The same antimicrobial regimens are recommended as for MRSA, although there are occasional reports of successful therapy with linezolid [174,175].

**Enterococci**

For many years, enterococcal endocarditis has been the one instance where the combination of penicillin, ampicillin, or vancomycin with an aminoglycoside (streptomycin or gentamicin) was required for clinical efficacy [176]. These recommendations have recently changed. The demonstration that ceftriaxone could be used for synergy in cases of endocarditis caused by high-level aminoglycoside-resistant (HLAR) *Enterococcus faecalis* was extended to include patients with non-HLAR enterococcal endocarditis with renal failure or a risk for nephrotoxicity [177]. An observational study comparing outcomes for patients who received ampicillin plus ceftriaxone or ampicillin plus gentamicin, as chosen by their treating physicians, found equivalent efficacy and much less toxicity for the double β-lactam combination [177,178]. Ceftriaxone provides synergy by binding to additional penicillin-binding proteins. This regimen is now recommended at the same level as the traditional combination of ampicillin plus an aminoglycoside in both U.S. [44] and European guidelines [103] and is the recommended therapy for HLAR strains of *E. faecalis*. However, it is not active against *E. faecium*. If the enterococcus is ampicillin-resistant due to β-lactamase production, one of the drugs that combine ampicillin or amoxicillin with a β-lactamase inhibitor (e.g., ampicillin–sulbactam) can be substituted, but if ampicillin resistance is not due to β-lactamase production, vancomycin must be used along with an aminoglycoside. Although the aminoglycoside has conventionally been recommended for the full duration of therapy, a retrospective study in Sweden found good results for patients who received only 15 days of aminoglycoside [179]. A subsequent study in Denmark, looking at outcomes before and after limiting the duration of aminoglycoside therapy to 2 weeks while continuing the β-lactam for a total of 4 to 6 weeks, found that patients receiving 2 and 6 weeks of aminoglycoside therapy had equivalent outcomes [180]. Recommended duration of combination therapy using penicillin or ampicillin with gentamicin for enterococcal NVE of less than 3 months’ duration is 4 weeks [44,103]. For disease of longer duration, prosthetic valve involvement, or vancomycin-based therapy, treatment is prolonged to 6 weeks with both drugs [44,103]. A 6-week course is also recommended for double β-lactam therapy for both native and prosthetic valve disease, as well as intracardiac device infection. The ceftriaxone dose is 2 g IV q12h, and that of ampicillin is 2 g IV q4h [44,103].

Endocarditis due to vancomycin-resistant enterococci (VRE) warrants
infectious disease consultation and may require specialized laboratory investigation \cite{44,181,182}. Daptomycin has in vitro activity against VRE, and time–kill curves demonstrated synergy with gentamicin and rifampin in a case where that combination was used \cite{183}. Quinupristin–dalfopristin is active only against \textit{E. faecium}, and in this series was never the sole component of successful therapy \cite{183}. The quinupristin–dalfopristin compassionate-plea program reported clinical and bacteriologic response in only 2 out of 10 (0 of 1 evaluable) patients \cite{184}. Linezolid 600 mg IV or orally every 12 hours proved successful in 10 (77\%) of 13 evaluable cases of VRE endocarditis (nine courses of therapy were not evaluable) \cite{185}.

**HACEK Organisms**

First-choice therapy for HACEK endocarditis is ceftriaxone 2 g IV every 24 hours (or other third- or fourth-generation cephalosporin) for 4 weeks in native valve disease and 6 weeks with prosthetic valves \cite{44}. Ampicillin–sulbactam may be used, but the combination of ampicillin and gentamicin is no longer recommended. Therapeutic failures with this combination in \textit{A. actinomycetemcomitans} endocarditis include a nearly 30\% mortality in one series \cite{186,187}. Ciprofloxacin at 500 mg orally every 12 hours or 400 mg IV every 8 hours is the suggested alternative for patients who cannot tolerate ceftriaxone or ampicillin–sulbactam \cite{44}.

**Candida**

\textit{Candida} endocarditis has generally been regarded as an indication for valve replacement surgery, but often the patients who get this infection have been too ill for surgery. Factors associated with survival of some of these high-risk patients in the absence of cardiac surgery include receiving initial combination antifungal therapy (most often amphotericin B plus 5-flucytosine) followed by long-term suppressive therapy with fluconazole \cite{188,189}. Case reports of good outcomes for patients treated with caspofungin, including four who did not have valve replacement \cite{190–192}, are now supported by a larger experience indicating that echinocandins are equally effective \cite{96}. Unfortunately, the mortality rate remains high (36\% in hospital and 59\% at 1 year), with no impact by choice of drug or performance of surgery in this series of 70 cases from 2000 to 2010 \cite{96}.

**Empiric Therapy**

Patients with endocarditis who require intensive care at admission will most likely have the acute form of the disease due to virulent pathogens
such as *S. aureus* or, more rarely, *Streptococcus pneumoniae* or pyogenic streptococci, unless they have undiagnosed subacute endocarditis and require intensive care due to cardiac or neurologic complications. Large emboli are a particular feature of HACEK, non-group A β-hemolytic streptococcal and candidal endocarditis. The British guideline is the only one that specifically addresses empiric therapy for the critically ill patient; it recommends vancomycin plus meropenem [104]. The AHA guideline suggests vancomycin and cefepime as the initial regimen for acute IE on native valves, to insure activity against aerobic Gram-negative bacilli [44], but given the small proportion of endocarditis cases (1% to 4%, Table 78.1) due to these organisms, providing treatment for enterococci may be a more important priority. Among patients with endocarditis admitted to ICUs in France from 2002 to 2012, enterococci were the etiology in 10.2% and Enterobacteriaceae in 4.7%. [39]. Enterococcus is the third most common etiology among injection drug users [9] and the cause of more than 10% (13% in North America [9]) of all cases of endocarditis in recent series [9,96]. The European guideline [103] suggests ampicillin, oxacillin, and gentamicin for community-acquired NVE while awaiting documentation of the etiology from blood cultures, but this would not be adequate in settings where oxacillin-resistant *S. aureus* (MRSA) is a major concern. Where that is the case, initial empiric therapy for community-acquired NVE for patients requiring intensive care, including injection drug users, might well consist of vancomycin, ceftriaxone (at the 2 g q12h dose), and ampicillin. This regimen should provide activity against staphylococci, viridans group (oral) and other streptococci, *Enterococcus faecalis*, and HACEK organisms.

Those who develop endocarditis after prolonged hospitalization have high rates of MRSA, enterococcal, and fungal endocarditis and may be the group at highest risk of non-HACEK Gram-negative bacillary endocarditis. Empiric antifungal therapy may also be considered for ICU patients who are on or have recently received prolonged courses of antimicrobial therapy. The lesser toxicity of echinocandin would favor use of one of these agents over amphotericin in this setting; they appeared to be equally efficacious in a study by the ICE investigators [96]. The same patients are among those with risk factors for extended-spectrum β-lactamase-producing Enterobacteriaceae or *P. aeruginosa*, for whom the British guideline recommendation may well have been intended.

All of the guidelines [44,103,104] agree on empiric therapy for PVE:
vancomycin, gentamicin, plus rifampin (with the suggestion that rifampin be deferred for the first several days in the European guideline) \[103\]. The U.S. guideline recommends the addition of cefepime for patients within the first year after prosthetic valve placement \[44\].

**Supportive Care and Monitoring**

Careful clinical monitoring of the patient on therapy for endocarditis includes surveillance for fever, evidence of congestive heart failure or other cardiac complication, metastatic infection, adverse effects of antimicrobial drugs (and levels, when appropriate), changes in renal function, and superinfection. Follow-up blood cultures should be obtained every 48 hours until they are repeatedly sterile. The duration of antimicrobial therapy is counted from the first day of blood culture negativity \[44\]. For aortic and mitral valve endocarditis, serial ECGs should be obtained to look for prolongation of the PR interval or other conduction abnormality that would signal invasion of the interventricular septum by the infection. Echocardiographic imaging should be repeated as described above to better define disease in patients whose initial echocardiography was unrevealing. It should also be repeated at any time when clinical changes, such as new murmur, embolism, persisting fever, heart failure, or atrioventricular block suggest poor control of disease or complications \[44,103\]; it may also be wise to repeat this study to detect new silent complications and follow vegetation size, especially for endocarditis caused by virulent organisms \[103\]. Echocardiography should also be repeated at the end of therapy as to define the patient’s new baseline \[44,103\].

Recrudescence of fever after initial resolution most often indicates a new problem outside the heart, such as catheter-associated sepsis, drug fever, or antibiotic-associated *Clostridium difficile* colitis, but superinfection of the endocarditic valve may occur. Unless there is another immediately obvious cause, persistent or recurrent fever should prompt repeat echocardiography.

The possible need for cardiac surgery mandates discontinuation of warfarin and substitution of heparin when the diagnosis of endocarditis is made for patients on anticoagulant therapy for prosthetic valves or other indications \[44\]. Anticoagulation in endocarditis carries the risk of converting bland emboli (infarcts) to hemorrhagic ones, and thus should be carefully monitored and continued with caution. When emboli with hemorrhage occur, anticoagulant therapy should be withheld for a period of time. The risk of central nervous system (CNS) hemorrhage in *S. aureus* PVE is so high that some recommend discontinuation of all anticoagulation during the acute phase of this illness \[193\].
Role of Cardiac Surgery

At times, failure of antibiotics to sterilize the blood necessitates surgical debridement and removal of the infected focus—the valve. Even if bacteriologic cure is achieved, some patients have sufficient valvular damage that they will die of hemodynamic compromise unless a valve is replaced. The surprisingly favorable outcomes of a number of patients operated on in these desperate circumstances have led to consideration of cardiac surgery much earlier in the course of endocarditis [194–197]. The two indications for surgery already mentioned—microbiologic failure and congestive heart failure—are now well accepted. The challenge is to identify patients who would eventually meet these criteria before their clinical condition deteriorates.

Harbingers of microbiologic failure include difficult-to-treat and aggressive organisms, such as *S. lugdunensis*, *S. aureus*, *P. aeruginosa* or other Gram-negative bacilli involving the aortic or mitral valve, and fungi, particularly molds. *C. burnetii*, *Bartonella*, *Brucella*, and other unusual organisms associated with true culture-negative endocarditis are also difficult to eradicate with antimicrobial therapy alone. The risk of microbiologic failure or relapse is elevated in the presence of prosthetic material, resulting in the recommendation for valve replacement in most cases of early PVE and the necessity of removing infected intracardiac devices such as pacemakers and other CIEDs. Conventional blood cultures should become sterile within 7 days after the institution of appropriate antibiotic therapy [44,93,192,197]. The median time for clearance of *S. aureus* varies among studies but may be as long as 9 days [167] but the surgical indication would be the duration of positive cultures, not simply the identification of this organism. Patients should defervesce within 9 to 10 days. Persistent fever may indicate continued active infection, myocardial abscess, or an embolic complication.

Many patients with endocarditis have preexisting congestive failure as a result of their underlying valvular disease, but new-onset or worsening heart failure carries an ominous prognosis—a mortality of 56% in one series [196]. Urgent surgery is indicated for these patients, and a number of authors have noted that medical stabilization may be impossible once severe progressive failure begins [196]. Acute aortic and mitral regurgitation, due to perforation, valve rupture, or paravalvular leak (in the case of PVE), are frequent mechanisms of congestive failure [197]. Valvular obstruction is less common but does occur on prosthetic valves and is an equally urgent indication for surgery. Rupture of sinus of Valsalva aneurysm into the right heart or pericardium also mandates surgery [198]. It cannot be overemphasized that once surgery is clearly indicated, it should not be delayed, because of the unpredictability of the clinical course and the increasing risk of the operation as failure...
progresses [196,197,199].

Echocardiography can be very helpful for defining the presence of complications that do require surgery, including destruction of the valve or extension of infection beyond the valve ring as a myocardial abscess. Myocardial abscess may be the reason for prolonged fever [197,200], lead to conduction defects [102,197], or cavitate into the pericardium with resultant purulent pericarditis [197]. Myocardial abscess is generally an indication for surgery to extirpate all infected tissue as well as correct the accompanying hemodynamic abnormalities [44,103,197,198]. Occasionally, abscesses that are less than 1 cm, that do not progress on therapy, and that are not complicated by disruption of other structures, may be followed with serial TEE and do not require surgery [44,197].

The risk of embolization is the most debatable indication for surgery. Although often viewed as an indication for surgery, this risk diminishes greatly over the first 2 weeks of antimicrobial therapy [44,103,197,198]. In one large study, 56% of embolic events in 629 patients with IE occurred before hospital admission or on the day antibiotic treatment started [201], and in another, only 7.3% of 384 patients had new embolic events after the initiation of therapy [202]. The difficulty lies in for defining when there is sufficient risk of clinically significant systemic or cerebral embolization to justify cardiac surgery not required for any other reason but before serious target organ damage has already occurred. There have been many attempts to establish echocardiographic predictors of embolization; vegetation length more than 10 mm by TEE was associated with a ninefold increase in risk of systemic or cerebral embolization on therapy and “severe mobility,” defined as “prolapsing vegetation that crosses the coaptation plane of the leaflets during the cardiac cycle,” with a 2.4-fold increase [202]. The U.S. guidelines deem one or more embolic events during the first 2 weeks of therapy a class I indication for surgery (condition for which there is evidence, general agreement, or both that a given procedure or treatment is useful and effective) [44]. Anterior mitral valve leaflet vegetations, especially those greater than 10 mm, and the presence of persistent vegetations after systemic embolization are class IIa indications (the weight of evidence/opinion is in favor of usefulness/efficacy), but increase in size of vegetation despite therapy is less well established as an indication for surgery [44]. European guidelines advise consideration of surgery for recurrent emboli despite adequate antibiotic therapy or mobile vegetations greater than 10 mm before or during the first week of antibiotic therapy [181]. U.S. experts recommend delaying valve surgery for a minimum of 2 weeks after a CNS embolic event [44,197] and at least a month after CNS hemorrhage [197], but European guidelines suggest that surgery can be performed within the first 72 hours of CNS embolism if a computed tomographic scan of the brain performed immediately
Right-sided endocarditis requires surgical intervention much less frequently than left-sided disease. In patients with isolated right-sided lesions, most often injection drug users, tricuspid vegetectomy, valve repair, or valvulectomy may permit cure of endocarditis due to resistant organisms without the risk of subsequent PVE. In the absence of pulmonary hypertension, tricuspid regurgitation may be tolerated without valve replacement [181,197].

The surgical approach for endocarditis is changing, with increasing interest in vegetectomy and valve repair rather than replacement. Repair is most often performed on the mitral valve and offers improved outcome over replacement [203,204]. Complete debridement of all infected tissue is mandatory. The reconstructive techniques developed for valve repair may also facilitate the surgical approach for cases with extensive perivalvular infection, where homografts and pericardial patches may be used to construct an annulus to which to attach a prosthetic valve when large amounts of normal tissue have been lost. The current view is that the risk of recurrent endocarditis on bioprosthetic and mechanical valve replacements is comparable, about 2% to 3% [44,181]. If valve cultures from surgery are negative, the duration of the antibiotic course originally planned should be completed, as long as it extends at least 7 to 15 days postoperatively. If intraoperative cultures are positive, the full recommended duration of antibiotics for the infecting organism should be administered counting from the day of surgery [44].

There is little difference in the clinical indications for surgery in native and PVE, but the proportion of patients requiring surgery is higher among those with prosthetic valves, approximately 50% [164,197,203,205–209]. Staphylococcal etiology and CNS embolization are uniformly identified as poor prognostic features. Early surgical intervention reduces the overall mortality of PVE [197,207,209]. Some studies have identified patients with PVE in whom medical therapy has equivalent outcomes to surgery as those with late-onset streptococcal disease who have no significant heart failure, no new valvular regurgitation or other intracardiac complication, and no CNS or systemic embolization [165,205,206]. Most important is that cardiac surgical treatment reduces the mortality rate among patients with poor prognostic factors to the level experienced by the patients with more favorable disease characteristics [164].

Comparison of outcomes of IE treated surgically versus medically have become more sophisticated, with matching for many variables, such as
age and comorbidities, propensity scores grading the likelihood of surgical therapy, and correction for survival bias, which is the negative impact of patients who die early in their hospital course(s) and are categorized as having received medical therapy alone, thus prejudicing the outcome of the nonsurgically treated group. Studies of the impacts of surgery using these methods do not present a uniform picture of its benefits. Apparent improvement in mortality became nonsignificant after these adjustments for some studies [210–212], but persisted in others [213–215], at least for some indications. For instance, patients with heart failure seemed to benefit from surgery (performed at a median of day 7) in one study [213], but not in another (also with surgery at a median of day 7 after admission), for which patients with valve perforation also did not benefit, although those with paravalvular complications, systemic embolization, S. aureus NVE, and stroke did [214]. Even at sites involved in major multicenter studies of endocarditis, substantially fewer patients had surgery than had conditions listed as surgical indications, but there is no way to determine how many of those had simultaneous contraindications or refused a recommendation for surgery [215,216].

A single randomized study of early surgery, performed within 48 hours of randomization (the discussion says “within 48 hours of diagnosis,” but the protocol excluded patients referred from another hospital more than 7 days after diagnosis, suggesting that patients would have been eligible as late as 7 days after diagnosis) enrolled patients with left-sided NVE, severe mitral or aortic valve disease, and a vegetation greater than 10 mm (thus, thought to be at high risk of emboli) [217]. The primary end point was in-hospital death or symptomatic embolic events confirmed by imaging within 6 weeks after randomization. Secondary end points at 6 months included death from any cause, embolic events, recurrence of IE, and need for readmission to the hospital for congestive heart failure. Of those randomized to conventional treatment, 77% underwent surgery during the initial hospitalization or follow-up (eight required surgery on an urgent basis, at a median of 6.5 days after randomization; 22 had elective procedures more than 2 weeks after randomization). One patient in each group died in the hospital, and eight patients in the conventional treatment group had emboli (all before valve surgery), a result favoring early surgery with \( p = 0.03 \) (hazard ratio 0.10, confidence interval [CI] 0.01 to 0.82). There was no significant difference in all-cause mortality at 6 months (3% vs. 5%); rate of the secondary end point at 6 months was 3% in the early surgery group and 28% in the conventional treatment group, \( p = 0.02 \) (hazard ratio 0.08, CI 0.02 to 0.65) [217]. The author of this study argues strongly in favor of surgery within 48 hours of diagnosis for endocarditis of those with “moderate to severe heart failure, uncontrolled infection, and large vegetations associated with severe valvular disease,” except for cases with intracerebral hemorrhage or large
cerebral infarction [218].

It is noteworthy that the mean (interquartile range) interval from admission to surgery was 18 [10–44,211] and 21 [9–37,212] days in two of the studies that showed no benefit for surgery after adjustment for survival bias (information on time to surgery not provided in [210]). In a direct comparison of surgery within the first week of antimicrobial therapy with procedures after that time, there was a decrease in 6-month mortality only for the quintile with the highest propensity for surgery (odds ratio 0.18, 95% CI 0.04 to 0.83, \( p = 0.03 \)). The patients in this group were younger, more likely to have \( S. \) aureus endocarditis, congestive heart failure, and larger vegetations; they were at higher risk of relapse and prosthetic valve dysfunction, as well [219]. By contrast, 59 patients with left-sided NVE and vegetations \( \geq 10 \) mm as the only indication for surgery who underwent early surgery at a mean of 5 ± 6 days following initiation of antimicrobial therapy had higher in-hospital (42% vs. 8%, \( p = 0.03 \)) as well as long-term mortality (59% vs 17, \( p = 0.007 \), at 6.0 ± 2.9 years) [220]. It should be noted that these patients appear to have had delayed diagnoses, with first symptoms of IE nearly 4 weeks before the start of antimicrobial therapy, so their surgery may not really have been early in the course; more than half had already had systemic emboli by the time of surgery and 16 (27%) had impaired mental status on admission. \( S. \) aureus was the etiology of endocarditis in 18 (32%) of the patients treated surgically, but only one (8%) of those treated medically. The decision for surgery was made on clinical grounds, presumably because of the severity of illness.

The variability of definition of “early surgery” is also a factor, as stressed by the only randomized clinical trial, in which patients with IE and severe aortic or mitral regurgitation were randomized to surgery within 48 hours or later, with improved 6-month survival for those who had valve replacement within the first 48 hours [217]. A retrospective review of patients who met criteria for valve replacement but did not undergo early surgery found endocarditis due to \( S. \) aureus less often treated surgically, largely because of the ongoing septic picture due to that organism [215]. High-risk surgical scores were another reason patients who had indications did not have cardiac surgery, but those at high risk who had surgery had marked improvement in survival compared to similar patients who did not, while patients with less than median surgical risk who underwent surgery fared at least as well as patients who had no indication for surgery and thus were treated only medically [215,216].
A meta-analysis of 21 reports from 1996 to 2015 [221] found that early surgery at ≤20 days was associated with decreased all-cause mortality compared to the group that did not receive surgery within the first 3 weeks, at a high level of statistical significance (p < 0.001), and also statistically significantly better than with medical therapy alone (p < 0.001). When the early surgery group was separated into those with surgery at ≤7 days and those with surgery at 8 to 20 days, both surgical groups had statistically significantly lower all-cause mortality than patients treated with medical therapy alone. Those who had surgery at ≥21 days had lower all-cause mortality than those who never had surgery, but the difference was not statistically significant. Analysis restricted to studies that used propensity weighting yielded the same findings, except that surgery at ≤20 days was statistically significantly better than later surgery (p = 0.008). In-hospital mortality was not different for groups receiving early (at <21 days) surgical intervention versus conventional therapy (meaning medical treatment with or without surgery at ≥21 days) in the 11 studies for which this outcome was available.

PVE has been thought to warrant surgery most of the time, but that may not always be true. A study of 1,025 patients, approximately half of whom had “early” surgery (during the initial hospitalization for endocarditis) found no difference in in-hospital or 1-year mortality when corrected for survival bias [222]. However, in-hospital mortality was lower with early surgery in the highest propensity quintile, and 1-year mortality was lower for both the fourth and fifth quintiles of surgical propensity (24.8% vs. 42.9% and 27.9% vs. 50.0%, respectively; p = 0.007 for both comparisons); however, these values were not corrected for survival bias [222]. More patients in the surgical group had congestive heart failure (36% vs. 29%), NYHA class III or IV heart failure (28% vs. 22%), and CoNS etiology (20% vs. 11%), but more patients in the medical therapy group had Enterococcus (17% vs. 9%). In a study limited to patients with S. aureus left-sided PVE, those who had surgery appeared to have significantly reduced 1-year mortality, but the significance did not persist in multivariate, propensity-based models (risk ratio 0.67, CI 0.39 to 1.15, p = 0.15) [223]. The fact is that for many cases, surgery for PVE is not elective but mandated by congestive failure, uncontrolled infection, and persistent sepsis. In this situation, current 30-day mortality rates are 12% to 14% and 5-year survival around 75% [224]. A prolonged period of symptoms without diagnosis and treatment increased risk, but duration of antibiotic therapy prior to surgery did not [224].

Neurologic complications of endocarditis do affect the decision on timing of surgery, but not necessarily whether it should be done. Given that valve surgery requires cardiopulmonary bypass with anticoagulation and may result in placement of a prosthetic valve requiring lifelong anticoagulation, there is justifiable concern that the cerebral lesions of
endocarditis could be worsened by bleeding during or after surgery. Consideration of valve surgery for endocarditis is one of the reasons to perform cerebral imaging, even in the absence of neurologic symptoms. Neuroimaging may also provide additional diagnostic information that mandates therapy, as in the case of discovery of unruptured mycotic aneurysms (also called infective intracranial aneurysms). Mycotic aneurysms were found in 32% of patients in a series from Egypt in which the mean duration of symptoms was 52.6 days (± standard deviation of 56.4 days) prior to presentation; 36% of patients with cerebral mycotic aneurysms were asymptomatic [225]. By comparison, a study in France using magnetic resonance imaging (MRI) found mycotic aneurysms in 8% (10 of 130 patients), confirmed by CT angiography in only four of the six in whom that was performed, for a corrected prevalence of 6% [226]. A study from Sweden using MRI with contrast (and CT with and without contrast in patients for whom MRI was contraindicated) identified mycotic aneurysm in only one patient (1.6% of a series of 60), who had subarachnoid bleeding due to its rupture at presentation after a 3-month delay of treatment [79]. These rates certainly suggest an association of mycotic cerebral aneurysm with prolonged duration of endocarditis prior to therapy. Obviously, unruptured aneurysms should be addressed before they bleed.

Studies using systematic neuroimaging have demonstrated cerebrovascular complications in 65% to 82% of patients with left-sided IE, of which 41% to 85% were silent [223,225–227]. In one series, four (16%) out of 25 patients with preoperative embolic stroke who had surgery during the active phase of endocarditis (while still on antimicrobial therapy) died in hospital, but the remaining 21 were long-term survivors (84%, compared to 95% of 166 patients without stroke) [228]. A larger series, comparing outcomes of valve surgery in 375 patients with IE and symptomatic or silent cerebral embolism over the period 1995 to 2012, found that 21.6% died within 30 days of surgery or while still in hospital, no different from the 19.7% of 1,196 patients undergoing valve surgery for endocarditis who had normal preoperative cranial CT scans [229]. The major cause of postoperative mortality was septic shock with multiple organ failure, followed by low cardiac output syndrome. Only 12 of the 375 patients died from cerebral complications, seven (less than 2% of the 375) of whom had severe intracerebral bleeding, the complication that is feared as a result of the surgery itself. In this study, there was no difference in either early (in-hospital) or late mortality between patients with silent and those with symptomatic cerebral emboli [229]. In a consecutive series of 64 patients with acute cerebral infarct due to endocarditis who underwent cardiac surgery, one patient who had cardiac surgery 2 days after multiple small cerebral infarcts had thalamic bleeding resulting in hemiplegia, one with surgery
at day 15 had small hemorrhagic transformation without neurologic deterioration, and one with surgery at 20 days suffered a new cerebral hemorrhage that proved fatal [227]. Three patients had ectopic hemorrhage detected only on postoperative neuroimaging: a small subarachnoid hemorrhage in a patient who had surgery on day 5 after infarct, and small subdural hemorrhages in two, following surgery at days 24 and 81 [227].

A large international study of 4,794 cases of IE from 2000 to 2006 [230] identified 857 patients with clinically overt stroke (defined as neurologic deficit of vascular origin lasting more than 24 hours), 556 of which were found to be ischemic on neuroimaging. 198 of these patients had cardiac surgery, 58 at 1 to 7 days after the stroke and the remainder later. Surgery within the first 7 days was not associated with higher in-hospital or 1-year mortality than later surgery after adjusting for other risk factors. The authors did not comment on hemorrhagic complications of surgery, but did state that their findings support performing cardiac surgery without delay when there is an indication for it [230]. A nationwide database study from Japan came to the same conclusion, based on a review of 253 patients with ischemic stroke due to endocarditis, using the same definitions of early and late surgery and both propensity-adjusted and inverse probability-weighted models [231].

The question of bleeding as a result of surgery is even more pressing for patients who have already had intracranial hemorrhage due to their endocarditis. A study from Japan included 30 such patients among 246 who underwent valve surgery for IE 2004 to 2012 [232]. Among the 30, 18 had cerebral hemorrhage, 8 subarachnoid hemorrhage, and 4 hemorrhagic infarction; 21 were symptomatic; all patients had preoperative brain CT on which the diagnoses were based. Eight had mycotic aneurysms, which were treated prior to valve surgery by either clipping or resection. Timing of valve surgery was decided by the individual patients’ surgeons, and was within 7 days of onset of the intracranial hemorrhage in five, 8 to 14 days in six, 15 to 28 days for nine, and more than 29 days for 10. There were no deaths from cerebrovascular complications and none of the patients had neurologic deterioration; however, four patients who underwent surgery 4, 25, 31, and 47 days after onset of intracranial hemorrhage died after surgery of cardiac failure or multiple organ dysfunction. Postoperative imaging showed no enlargement of any of the preexisting hemorrhagic areas, although some patients had new small areas of hemorrhage [232]. This study also includes a literature review, indicating that neurologic deterioration
occurred in 1/9 previously reported patients who had valve surgery within 0 to 14 days of intracranial hemorrhage, in 0/15 with surgery at 15 to 28 days, and in 1/29 with surgery at 29 days or later.

Both the AHA and the European Heart Society (EHS) published revised treatment guidelines for IE, including the role of surgery and its timing after neurologic events, in the fall of 2015. The AHA [44] and EHS [103] guidelines are in complete agreement about the indications for surgery in right-sided endocarditis. These are:

1. Right-sided heart failure due to severe tricuspid regurgitation with poor response to medical (diuretic) therapy.

2. Organisms that are difficult to eradicate: EHS would base this on the organism isolated (e.g., persistent fungi), whereas the AHA specifies sustained infection (presumably, prolonged duration of positive blood cultures) caused by difficult-to-treat organisms (i.e., fungi, multidrug-resistant bacteria).

3. Clinical failure: EHS specifies bacteremia for at least 7 days despite adequate antimicrobial therapy, which would meet the AHA criterion of lack of response to appropriate antimicrobial therapy.

4. Large tricuspid vegetation (>20 mm) with recurrent pulmonary embolism. EHS specifies that the vegetation persists after pulmonary emboli, whereas AHA defines this as recurrent pulmonary embolism despite antimicrobial therapy.

They both recommend repair over valve replacement whenever possible, because of the risk of reinfection from continued injection drug use.

Their conclusions regarding the indications for surgery in left-sided IE are also very similar, although their views of the strength of the evidence differ slightly, and only the EHS guidelines specify timing of surgery. Table 78.4 presents the indications for surgery as well as the class of recommendation for each and the timing for intervention recommended by the EHS. The AHA guidelines use the term “early surgery” to mean valve surgery during the initial hospitalization and before completion of a full course of antibiotics for endocarditis, whereas the EHS is more specific: “emergent” means within 24 hours, “urgent” means “within a few days, <7 days,” and elective means after at least 1 to 2 weeks of antibiotic therapy. They both classify the level of recommendation based on the robustness of the studies; the EHS also considers the degree of agreement among experts in their system. Both provide suggested wording to describe the strength of each recommendation:

Both guidelines recommend that cardiac surgery be postponed for at least 4 weeks (AHA)/1 month (EHS) following intracranial hemorrhage or presence of coma following (AHA “major”) ischemic stroke (class IIa), but may proceed without delay after ischemic stroke if presence of cerebral hemorrhage has been excluded by cranial CT or MRI and coma is absent (EHS, class IIa; AHA wording “if neurologic damage is not severe [i.e., coma]” class IIb).

NA = not addressed.

Class I means the procedure “is recommended/is indicated” in the EHS document and “should be performed/administered” in the AHA one.

Class IIa means “should be considered” (EHS) or “is reasonable,” “can be useful/effective/beneficial,” “is probably recommended or indicated” (AHA).

Class IIb means “may be considered” in both.

Thus, both consider heart failure due to severe regurgitation, obstruction, or fistula a class I indication; if this is causing refractory pulmonary edema or cardiogenic shock, it requires immediate surgery, whereas if the regurgitation or obstruction is causing symptoms of heart failure or echocardiographic signs of poor hemodynamic tolerance, surgery should be performed within a few days, no more than a week.

The category of uncontrolled infection includes anatomic evidence of progression, such as the development of annular or aortic abscess (which may be evidenced by heart block), destructive penetrating lesions (fistulae), aneurysms and false aneurysms, which both guidelines consider a class I indication for surgery. The EHS also includes enlarging vegetations in this group and considers these findings to require urgent, but not emergent, surgery. Organisms known to be difficult to control, including fungi, VRE, and multidrug-resistant Gram-negative bacilli, are class I indications for surgery for both AHA and EHS, with timing that may be urgent or elective. Clinical evidence of uncontrolled infection, such as persistent positive blood cultures despite appropriate antimicrobial therapy and drainage or extirpation of sites of metastatic
infection (e.g., splenic abscess) are class I indications in the U.S. guidelines, along with persistence of fever beyond 5 to 7 days, but IIa in the European ones, with timing of surgery urgent (EHS). The EHS considers PVE caused by staphylococci or non-HACEK Gram-negative bacilli to be a class IIa indication for surgery which may be either urgent or elective, but the AHA does not, although PVE caused by staphylococci or non-HACEK Gram-negative bacilli is a class IIa indication for urgent or elective surgery in both guidelines. The U.S. guidelines also consider relapsing PVE a class IIa indication, but this criterion is not mentioned in the European ones.

Both sources also see prevention of embolism as an indication for surgery. The specific criteria differ a little, as do the interpretations of the strength of the evidence. Persistent vegetations > 10 mm after one or more embolic episodes occurring despite appropriate antibiotic therapy are a class I indication for urgent surgery according to EHS and class IIa for the AHA. NVE with vegetations >10 mm associated with severe valvular stenosis or regurgitation is a class IIa indication in patients with low operative risk (EHS; timing urgent) or when the vegetation is mobile (AHA). Isolated vegetations > 15 mm with no other indication for surgery is a class IIb indication for the EHS (urgent), while a mobile vegetation > 10 mm, especially on the anterior leaflet of the mitral valve, along with other relative indications for surgery, is a class IIb indication for the AHA.

Individual patient situations may modify the readiness to resort to surgery. For instance, for a patient with another condition that makes the risk of general anesthesia prohibitive, such as severe restrictive lung disease, one might elect to operate only in the event of congestive heart failure. The guidelines for surgical intervention are not absolute predictors of failure of medical management but overall can predict low rates of success.

In summary, therapy for endocarditis requires skillful manipulation of antibiotics and careful day-to-day judgments of the relative risks of expectant versus surgical management. It should be stressed that among cases with any adverse prognostic features, including all patients with staphylococcal or PVE, it is wise to make provisions for possible urgent surgery early in the course. This includes discussions of surgery with the patient and family and consultation with the cardiac surgical team. Table 78.5 provides a summary of recommendations for management of endocarditis supported by randomized controlled clinical trials.
TABLE 78.5 Summary Recommendations for Management of Endocarditis Based on Randomized Clinical Trials

- NVE caused by highly penicillin-susceptible viridans streptococci or *Streptococcus bovis* is effectively treated with a 2-wk regimen of ceftriaxone 2 g every 24 h IV with gentamicin 3 mg/kg/24 h IV given in a single dose [165]

- Addition of 2 wk of gentamicin to 4 wk of oxacillin or nafcillin therapy for methicillin-susceptible *Staphylococcus aureus* endocarditis does not improve outcome [166,167]

- Uncomplicated tricuspid valve endocarditis caused by methicillin-susceptible *Staphylococcus aureus* is effectively treated with a 2-wk regimen of either nafcillin or oxacillin 12 g/24 h IV in four to six equally divided doses [44], based on a trial comparing cloxacillin 2 g IV q4h with and without gentamicin 1 mg/kg IV q8h in injection drug users [168]

INTRODUCTION

As US health care payment structures are shifting toward quality rather than quantity of care, health care-associated infections have come to the forefront as targets for infection prevention. Significant efforts to reduce the burden of health care-associated infections have included multistep prevention bundles and encouraging line removal wherever possible, but despite these efforts, 1 in 25 inpatients has a health care-associated infection [1]. Intensive care unit (ICU) patients account for 80,000 central line-associated bloodstream infections (CLABSI) per year. Each infection can cost up to $56,000 and have an attributable mortality of up to 40% [2]. Groups such as the National Healthcare Safety Network (NHSN) compare hospital CLABSI rates, and hospitals in the lowest-performing quartile can have funds withheld because of these performance measures.

Guidelines for the prevention and treatment of catheter-associated infections have been updated in the past few years [3–5]. Recommendations in this chapter are based on these published guidelines. The reader is referred to these publications for a more in-depth review of the topics of prevention, diagnosis, and treatment of catheter-associated infections.
PATHOGENESIS OF CATHETER-RELATED INFECTION

Foreign bodies that penetrate the cutaneous barriers of the host induce a chronic inflammatory response and are coated with host proteins, including fibronectin, fibrin, and laminin [6]. The coated catheter provides a niche for microorganisms that adhere by fimbriae and adhesins that bind to surface receptors present on some of the coating proteins, or by electromagnetic interactions leading to the formation of biofilms within days of insertion [6].

Microorganisms gain entry to the catheter primarily at the insertion site. Particularly in catheters used short term, there is a correlation between organisms isolated from the catheter and those obtained from the insertion site [3]. Contamination of the catheter hub and ultimately the internal lumen of the catheter plays a larger role in the development of infections of catheters remaining in place for more than a month [3,6]. Less commonly, catheter-associated infections occur as a result of hematogenous seeding from a distant focus of infection or from a contaminated infusate.
The diagnosis of catheter-associated infection still relies primarily on the recognition of clinical signs and symptoms of a patient who has an intravascular device in place, absence of an alternative cause for those clinical findings, and microbiological evidence for infection [5]. The clinical signs noted for some, but not all, patients with a catheter-associated infection are development of warmth, erythema, and pain at the site of current or recent catheter placement. Patients with catheter-associated bloodstream infection generally have fever, with or without hypotension and other signs of sepsis. Finding microorganisms when a catheter tip is submitted for culture from an asymptomatic patient is not indicative of infection; conversely, impressive local findings may reflect only phlebitis or reaction to the infusate. Thus, differentiating catheter-associated infection from colonization of the catheter can be difficult, and no perfect diagnostic method has been established.

**Blood Culture with Catheter Retention**

Positive blood cultures from a patient who has an indwelling vascular catheter and no other obvious source of infection raises the possibility of a catheter-associated infection. A variety of approaches have been devised to help differentiate whether a positive blood culture represents catheter-associated infection or has arisen from another source. Quantitative cultures of blood taken simultaneously from the catheter and from peripheral blood that demonstrate a difference of at least threefold more microorganisms from the catheter is probably the most accurate method to determine if catheter-associated infection is present without removing the catheter [7,8]. However, few clinical laboratories routinely perform quantitative blood cultures.

Differential time to positivity of blood cultures taken from a central line compared with those taken from a peripheral vein is another diagnostic method. Blood cultures obtained from an infected central catheter may turn positive at least 2 hours sooner than blood drawn simultaneously from a peripheral vein [8]. Another method that does not require the removal of the catheter involves culture of peripheral blood as well as the insertion site and hub. Growth of more than 15 colonies of the same organism from all three sites suggests catheter-related infection [5,9].

It is important to minimize the possibility of contamination when obtaining blood for culture by having specifically trained personnel
obtain the samples. Disinfection of the skin and hub using an alcoholic chlorhexidine antiseptic, not povidone–iodine, is recommended [3,4]. Blood samples taken from a peripheral vein are less likely to be contaminated than blood samples obtained from the catheter [10]. All of the techniques listed above require sampling from the catheter as well as from a peripheral vein. Additionally, all catheter lumens should be sampled to increase the sensitivity of diagnosis of catheter-related infection [11].

Catheter Culture Following Catheter Removal

Although culture of the catheter is very helpful for the diagnosis of catheter-associated infection, it necessitates removal of the catheter before the diagnosis can be made. For optimum culture, the catheter tip should be cultured. Quantitative cultures obtained by sonication of the catheter tip have been advocated as a more accurate method to determine the numbers of microorganisms present on both the internal and external surfaces of the catheter [5]. However, others have shown no benefit of the more complicated sonication method over the roll-plate method [12].

Rolling the distal segment of the catheter on an agar plate yields semiquantitative results that compare favorably with quantitative methods and has gained the greatest acceptance [5,7]. The presence of ≥15 bacterial colonies on an agar plate correlates significantly with the presence of local inflammation and signs and symptoms of bloodstream infection. No similar cutoff has been established when yeasts are grown from the catheter tip. A drawback of this technique is that only the external portion of the catheter is cultured, not the lumen, which may be the primary site of infection for long-term catheters. For short-term catheters, the roll-plate technique is the recommended microbiologic method for diagnosis of catheter-related infection [5,7].

Types of Catheters

Nontunneled Central Venous Catheters

These catheters are inserted into the subclavian vein, the internal jugular vein, and rarely the femoral vein. They can be single or multilumen depending on the specific needs of each patient. Some studies, but not all, have shown that multilumen catheters are associated with a higher rate of colonization and infection than single-lumen catheters, particularly when used for an extended period of time [13–15]. Increased risk for infection,
especially with multilumen catheters, occurs with the frequent manipulations that are required in the care of critically ill patients. It is recommended that a central venous catheter be chosen with the minimum number of ports or lumens required for the care of the patient [4]. Care of these multilumen lines should be limited to a few well-trained personnel [4]. Multiple indwelling central venous catheters also increase the risk of infection, and removal of unnecessary lines should be considered on a daily basis [4,16–18]. Nontunneled central venous catheters should be used predominantly for patients in the ICU.

Antimicrobial Impregnated or Coated Central Venous Catheters

Numerous antimicrobial agents (tetracyclines, rifamycins, glycopeptides, $\beta$-lactams, and echinocandins), antiseptics (benzalkonium chloride, chlorhexidine, tridodecylmethylammonium chloride, iodine, gentian violet, and silver molecules), and antithrombotic agents (heparin and ethylenediaminetetraacetate [EDTA]) alone or in various combinations have been bound to polymer material or used to coat the surfaces of catheters in the hope of reducing colonization, thrombosis, and subsequent infection [3,4,7,19–21]. Heparin-coated catheters should not be used because of concerns for developing heparin-induced thrombocytopenia [21].

Minocycline–rifampin-coated catheters (Cook Medical, Bloomington, IN), chlorhexidine–silver sulfadiazine-coated catheters (Arrow International, Reading, PA), and a silver–platinum–carbon impregnated catheter (Vantex, Edwards Life Sciences, Irvine, CA) are currently available. All of these catheters have been shown to reduce catheter-associated colonization [4,7,19]. In some controlled trials, the rates of catheter-associated bacteremia were sufficient to demonstrate significant reductions of infection rates when antimicrobial catheters were compared with standard catheters [4,7,22,23]. The recommendations are to strongly consider the use of antimicrobial-coated catheters for adult patients who will likely require a central catheter for 5 to 14 days, if the local rate of catheter-associated bloodstream infections is unacceptably high in spite of adherence to other measures, such as maximal sterile barriers and use of chlorhexidine antisepsis [3,7,19]. Use of these catheters also could be considered for patients who have limited venous access and a history of recurrent catheter-related infections and for those with increased risk for severe sequelae if they develop systemic infections, such as patients with recently implanted devices [3]. Each hospital must decide, based on their rates of catheter-associated bloodstream infection, whether the higher costs of purchasing antimicrobial-coated catheters are justified.
Peripherally Inserted Central Venous Catheters

Peripherally inserted central venous catheters (PICC) have become increasingly common for venous access. PICCs were initially thought to have lower rates of infectious complications when compared to other central venous catheters. PICCs may have a lower risk of infection in outpatients, but the infection risk in hospitalized patients is comparable to that with central venous catheters [4,11,24,25]. Initial insertion costs are lower than those for tunneled central venous catheters, but rates of mechanical complications and phlebitis can be higher. These catheters must be inserted by specially trained health care workers or interventional radiologists. A PICC can be left in place for weeks to months as long as there is no malfunction; evidence of phlebitis; or infection.

Semipermanent Tunneled Catheters (Long-Term Central Venous Catheters)

Cuffed double-lumen subclavian catheters tunneled subcutaneously are used primarily for infusing parenteral nutrition solutions and cancer chemotherapy. The risk of infection with semipermanent tunneled catheters appears to be low [5,7]. Routine use in the ICU is not practical.

Pulmonary Artery Catheters

Use of pulmonary artery catheters has decreased markedly in the last decade because of the introduction of new hemodynamic monitoring technologies. The approach to placement and maintenance of these catheters in patients who have an appropriate indication should generally follow established guidelines for central line placement [3].

Peripheral Arterial Catheters

Although peripheral arterial catheters were initially believed to have lower risk of catheter-related infection, indwelling arterial catheters appear to have rates of complications similar to those for venous catheters [3,26]. Signs and symptoms of infection for arterial catheters are similar to those for venous catheters; however, the absence of local signs of inflammation does not preclude infection. Distal embolic lesions and hemorrhage are highly predictive of arterial catheter-associated bloodstream infection. Late complications such as pseudoaneurysm formation and rupture of the artery may occur [27]. The longer the catheter remains in place, the higher the rate of bloodstream infection.
Midline Catheters

Midline catheters are 3 to 8 inches in length, are inserted into the antecubital fossa or upper arm veins, and extend no further than the distal portion of the subclavian vein. These catheters are ideal if infusions are required for 6 to 14 days for non–critically ill patients [25]. They can remain in place for 4 weeks, are convenient to insert, are associated with fewer infections than central venous catheters, and cause less phlebitis than peripheral catheters [3]. However, infusions that irritate the vascular endothelium, such as vancomycin, nafcillin, and amphotericin B, cannot be given through this type of catheter.

Catheter Insertion

Choice of Insertion Site

Regardless of the type of catheter inserted, the major risk factor for the development of catheter-associated infection is the breach of a major host defense against infection—the skin. Catheter-associated infections are usually because of organisms colonizing the skin, particularly gram-positive cocci, such as coagulase-negative staphylococci and Staphylococcus aureus. However, the distribution of microorganisms on the skin varies. For example, gram-negative bacilli, Candida spp., and anaerobes are increased in the groin area and on the lower extremities. The human microbiome is altered by illness, hospitalization, and the presence of foreign bodies.

The use of antimicrobial agents contributes to the emergence of resistant gram-positive and gram-negative organisms and yeasts. Daily disinfection of patient skin with chlorhexidine wipes or baths has been effective for reducing colonization and ultimately bloodstream infections in ICU patients [28,29]. Patients who have a productive cough or a tracheostomy can easily contaminate their skin with organisms from their respiratory tract [30].

The site of catheter insertion influences the risk of infection. Central venous catheters inserted in the internal jugular and femoral veins are associated with bloodstream infection significantly more often than those inserted into the subclavian vein [31]. Increased risk of thrombosis, contamination, and difficulties in dressing the site may play a role [4,31]. Insertion site colonization risk is particularly increased among obese
patients with femoral catheters and for patients with tracheostomies with jugular catheters [3,30,32]. Risk of pneumothorax is more common among patients who have subclavian catheters; insertion using ultrasound guidance may help limit this complication [4,33]. Decisions regarding insertion site must be based on the risks of mechanical complications versus infectious and thrombotic risks. For long-term catheters, for which the risks of infection and thrombosis increase with duration of catheterization, use of the subclavian site is preferred [4,31]. All catheters should be removed as promptly as possible especially if they are inserted emergently under less than sterile conditions or if the catheter is no longer needed [3,4].

Insertion Techniques

It is essential that health care personnel perform hand hygiene with an alcohol-based waterless product or washing with antiseptic soap and water prior to insertion of a catheter [3,4,34]. Use of gloves is not a substitute for hand hygiene. Catheter-associated phlebitis and infection are more likely to occur when catheters are inserted by inexperienced personnel rather than personnel who are trained in these techniques.

Prospective, randomized trials have shown that strict adherence to sterile technique (i.e., mask, cap, and large sterile drape, gloves, and gown) is beneficial for preventing central venous catheter infections, and also highly cost-effective [3,4]. The importance of sterile techniques using maximal barrier precautions for short-term central catheters cannot be overemphasized and should become a part of house staff training [3,4]. Use of a standardized catheter cart or kit that contains all of the equipment necessary to insert a central venous catheter and use of a hospital-specific bundle or catheter insertion checklist filled out by a trained observer to ensure and document adherence to infection prevention practices at the time of insertion are recommended [3,4,16]. Health care personnel should be empowered to stop the catheter insertion if any breach in aseptic technique is observed.

Ultrasound guidance for the insertion of central vascular catheters, especially internal jugular catheters, has been shown to reduce the risk of infection [3,4,33].

Cutaneous Antisepsis

Chlorhexidine and iodine-based solutions, alone or in combination with alcohol, have been used to reduce microbial contamination at the insertion site of the catheter [3,4]. Current recommendations include the application of alcoholic chlorhexidine antiseptic (0.5% chlorhexidine gluconate) to the insertion site; the site should be allowed to dry before
catheter insertion [3,4,35]. Chlorhexidine products should be used with care in children less than 2 months of age [3].

Antimicrobial ointments have been shown to increase the risk of infection with Candida and antibiotic-resistant bacteria and may affect the integrity of some catheters. With the exception of povidone–iodine ointment for some hemodialysis catheters, routine use of ointments at the catheter insertion site is discouraged [3,4].

A chlorhexidine-impregnated patch (BIOPATCH, Ethicon, Somerville, NJ) has been shown by a randomized controlled trial to reduce colonization at the catheter site and to reduce catheter-related bloodstream infections [36]. However, several guidelines do not recommend routine use of this patch, but rather suggest that it can be considered for use when the rates of catheter-associated infection remain high despite consistent use of evidence-based prevention bundles [3,4]. Use of these patches could be considered for patients who have limited access and a history of recurrent catheter-associated infections and for those who have a heightened risk of severe sequelae if infection should occur [3]. The use of systemic antibiotics as prophylaxis before the placement of central venous devices is strongly discouraged because selection for antibiotic-resistant microorganisms is highly likely [3,4].

Care of the Catheter and Insertion Site

Insertion Site Dressings

Either gauze and tape bandages or transparent semi-permeable dressings can be used for peripheral and central catheters. Transparent dressings are changed every 5 to 7 days and gauze dressings every 2 days or more frequently if the dressing is soiled, loose, or damp [3]. Site care should be performed with a chlorhexidine-based antiseptic with each dressing change [3]. At some centers, chlorhexidine patches are placed over catheters during routine dressing changes.

Catheter Hub Disinfection

Local disinfection of the hubs of central venous catheters must be performed using either a chlorhexidine-based preparation or 70% alcohol before attempting access [3,4]. With either preparation, it is very important to allow the antiseptic to dry to ensure antimicrobial activity before accessing the catheter. Maintenance of the catheter hub should be performed with strict standards, similar to those for insertion of catheters, to decrease the risk of contamination and infection [4]. A randomized controlled trial found that reducing the frequency of changing unsoiled adherent dressings from 3 to 7 days, and thus
decreasing manipulation of the site, did not increase the risk of infection [36].

Catheter Replacement

Peripheral Catheters

Phlebitis of a peripheral vein is a well-recognized harbinger of infection and may be quite uncomfortable for the patient. A catheter causing phlebitis should be removed promptly and the tip cultured. Complications of peripheral venous catheter insertion, including phlebitis and catheter-associated infection, increase after 72 hours of insertion. Recommendations to remove and change these catheters to another site every 72 hours are aimed at decreasing the risk for infection and the discomfort associated with phlebitis [4]. Midline catheters and PICC lines should not be removed and changed routinely unless phlebitis or signs of infection develop [4].

Central Catheters

The risk of infection increases during the time that a central catheter is in place, but several studies have shown that routine replacement of these catheters does not reduce rates of catheter-associated bloodstream infections [3,4]. Routine rotation of a central catheter to a different site is associated with increased risk for pneumothorax, laceration of a vessel with hemothorax, and arrhythmias and thus, is not recommended [5].

The use of routine catheter change over a guidewire has also been tried as a means to decrease catheter-related infections. However, a meta-analysis of studies employing this technique failed to show an effect on decreasing infections, and routine catheter changes over a guidewire are not recommended [4,37]. Thrombosis requires removal of an indwelling catheter [38]. An exception is made for the patient who has poor access and is dependent on a surgically implanted semipermanent central catheter. Under these circumstances, an attempt to salvage the catheter is reasonable [5].

Infusion-Related Issues
Local Effects

Intravenous solutions and drugs that are acidic, hypertonic, or directly irritating to vascular endothelium (KCl, certain antibiotics, and chemotherapeutic agents) may lead to a local inflammatory response, thrombosis, and phlebitis, with an increased risk of infection. When such infusions are necessary, a central catheter should be used.

In-Line Devices and Filters

In-line devices can be a significant source of catheter-associated infections. Pressure transducers have been implicated during outbreaks of catheter-associated bloodstream infection, particularly those due to water-associated gram-negative bacilli, including *Pseudomonas, Serratia, Enterobacter, Citrobacter*, and *Acinetobacter* spp. [39]. Stopcocks are easily contaminated through manipulation by personnel or by injection with contaminated syringes and may be an important source of infection; use of a closed system rather than stopcocks has been shown to lead to less contamination of the line. Some studies suggest that needleless mechanical valve devices may pose a greater risk of infection than split septum devices [40,41]. Disposable transducer domes, stopcocks, needleless components, and other in-line devices should be changed with the rest of the infusion set. In-line filters do not decrease the rate of infection, and their use is not recommended [4]. All catheter hubs, needleless connectors, and injection ports should be disinfected with a chlorhexidine preparation before accessing the device [3].

Contamination of Infusates

Breaks in sterile technique by hospital personnel can cause bloodstream infection. Gram-negative bacilli, such as *Enterobacter, Klebsiella, Serratia*, and *Citrobacter*, can proliferate in the acidic environment of intravenous fluids containing minimal nutrients, and other organisms, including fungi, can grow in parenteral nutrition infusates containing lipids [42,43].

Multifaceted Approach to Prevention of Catheter Infection

An optimal approach to prevent catheter-associated infection involves the use of multiple infection control strategies, often termed a bundle. In Michigan, 108 ICUs assessed the impact of five-evidence based procedures recommended by the Centers for Disease Control and Prevention to prevent catheter-associated bloodstream infection [44].
This bundle consisted of full-barrier precautions for catheter insertion; hand washing; insertion site cleansing with chlorhexidine; avoidance of femoral insertion site; and removal of unnecessary catheters. This was implemented in conjunction with clinician education, use of a designated central-line cart, a checklist to ensure adherence, and empowerment of the assistant to stop the procedure if the practices in the bundle were not being followed. This intervention led to a sustained 66% reduction in catheter-associated bloodstream infections over 18 months. Subsequent reports verified the efficacy of this approach [45–47]. The “bundle” approach has become standard of care and has been incorporated into practice guidelines [3,4,16]. Advances of prevention of infections associated with vascular catheters are summarized in Table 79.1.

**TABLE 79.1 Summary of Recommendations for Prevention of Central Venous Catheter-Associated Infections Based on SHEA/IDSA Guidelines [3]**

- Bathe intensive care unit patients with chlorhexidine daily (grade of evidence: I)
- Document adherence to infection prevention practices at the time of catheter insertion by a checklist filled out by a trained observer (II)
- Perform hand hygiene prior to insertion or manipulation of the catheter (grade of evidence: II)
- Use maximal sterile barriers (sterile full-sized drape, sterile gown, sterile gloves, face mask, and head cap) during insertion (II)
- Perform insertion site antisepsis with chlorhexidine (grade of evidence: I)
- Consider the use of a chlorhexidine-impregnated patch at the insertion site (grade of evidence: I)
- Change transparent dressings and perform site care with chlorhexidine-based antiseptic every 5–7 days or immediately if dressing is soiled, loose, or damp (grade of evidence: II)
- Do not routinely replace central intravascular catheters (grade of evidence: I)
- Consider use of central intravascular catheters coated with antimicrobial agents (minocycline–rifampin) or
chlorhexidine–silver sulfadiazine when infection rates are high (grade of evidence: I)

I, high quality; II, moderate quality.
Grade of quality of evidence is from SHEA/IDSA Practice Recommendation [3].
CATHETER-ASSOCIATED INFECTIONS

Microbiology
Coagulase-negative staphylococci (S. epidermidis and other species) are the most common organisms implicated in catheter-associated infections, followed by S. aureus; a variety of gram-negative bacilli; other gram-positive cocci and bacilli; and Candida and other yeasts [5]. Coagulase-negative staphylococci are associated with less severe disease than most other organisms. S. aureus bloodstream infection is most likely to cause complications, including endocarditis, and Candida spp. have a propensity to seed to other structures, such as the eye [48,49].

Complications
Major complications of catheter-associated infections include septic shock, suppurative phlebitis, metastatic infection, endocarditis, and arteritis. These complications often require aggressive management that combines appropriate antimicrobial therapy and surgical intervention. Complications of bloodstream infection should be suspected, especially if the catheter has been removed, when a patient has persistence or relapse of the same organism by blood cultures after 72 hours of appropriate medical therapy and no alternative explanation can be found.

Suppurative Phlebitis
Suppurative phlebitis associated with vascular catheters is manifested by fever and positive blood cultures; signs of phlebitis may not be obvious. For peripheral catheters, old healed insertion sites may require exploration by needle aspiration or incision. Suppurative phlebitis of central veins, particularly of the subclavian veins and superior vena cava, should be confirmed by detection of a thrombus by computerized tomography, magnetic resonance imaging, venography, or ultrasound. Surgical or interventional radiological procedures to remove the thrombus are technically difficult, but should be considered when bloodstream infection persists despite conservative management. Most patients will respond to 3 to 4 weeks of treatment with systemic antimicrobial therapy.
Endocarditis

Endocarditis is a dreaded complication of catheter-associated infections, and is most likely to occur with infection with *S. aureus*. The aortic and mitral valves are involved most often; normal valves, as well as previously damaged valves, can be infected. Right atrial catheters that cross the tricuspid valve can cause endothelial damage and turbulence, predisposing the patient to the development of right-sided endocarditis if bacteremia or fungemia occurs. Persistent or intermittent bacteremia or fungemia despite catheter removal; and evidence of pulmonary, cutaneous, central nervous system, or other embolic phenomena suggest a diagnosis of endocarditis.

Initial Treatment

In the febrile patient in whom catheter-associated bloodstream infection is suspected, empiric treatment should include antimicrobial agents that cover both gram-positive cocci and gram-negative bacilli \[^5\]. Vancomycin is chosen most frequently because of its activity against methicillin-resistant *Staphylococcus aureus* (MRSA) and coagulase-negative staphylococci. An alternative agent, such as daptomycin, should be considered in settings in which MRSA isolates commonly have vancomycin minimum inhibitory concentrations (MICs) ≥2 µg per mL. For gram-negative bacilli, the choice of a β-lactam–β-lactamase inhibitor combination, an anti-pseudomonal cephalosporin, or a carbapenem should be based on local antimicrobial susceptibility data.

Use of an antifungal agent, preferably an echinocandin, should be considered for patients who have risk factors for candidemia, including a hematologic malignancy or solid organ transplant, presence of a femoral catheter; who are receiving parenteral nutrition and/or broad-spectrum antibiotic therapy; who have had recent abdominal surgery; and who are known to be colonized with *Candida* spp. \[^{49}\]. Once the organism has been identified, the appropriate antimicrobial therapy should be chosen based on antimicrobial susceptibilities (Table 79.2).

**Staphylococcus Aureus Infections**

It is difficult to distinguish uncomplicated from complicated catheter-associated *S. aureus* bloodstream infections and to predict which patients have endocarditis [50,51]. It is recommended that transthoracic echocardiography (TTE) be performed in all cases of catheter-associated *S. aureus* bacteremia [52]. For many patients, the TTE is equivocal, and transesophageal echocardiography (TEE) should be performed to better define the presence of vegetations and other cardiac abnormalities. Because TEE is invasive, several experts have suggested that a TEE might
best be done only for those patients at highest risk for having endocarditis, which in one study was defined as those who have persistent bacteremia ≥4 days duration or in whom there is a permanent intracardiac device [51,53]. If the catheter is promptly removed and TEE is negative for vegetations, S. aureus bacteremia can be treated with a minimum of 2 weeks of a penicillinase-resistant β-lactam antibiotic or a first-generation cephalosporin; vancomycin or daptomycin should be used for MRSA. However, even those patients who appear to be appropriate candidates for short-course therapy may later present with metastatic foci, so it is essential to reassess “uncomplicated” cases if fever or embolic phenomena occur and certainly when follow-up blood cultures also yield S. aureus [5].

Candida spp. Infections

Current recommendations are to treat all patients with catheter-associated fungemia with an antifungal agent [49]. The possibility that the organism has seeded to distant sites, especially the eye, is high, leading to the recommendation that all candidemic patients should have a dilated retinal examination, preferably by an ophthalmologist [49]. Most studies have found that outcomes are improved when the catheter is promptly removed, but the argument has been made that for most many patients with neutropenia, the gut is the source of candidemia, and the catheter does not have to be removed. Many of these patients are thrombocytopenic, and the tunneled catheter or indwelling port cannot be removed easily. However, in the nonneutropenic patient, the recommendation is to remove all central catheters as soon as possible when feasible [49]. Treatment with an echinocandin (anidulafungin, caspofungin, and micafungin) is recommended; fluconazole can be used when the organism has been shown to be susceptible. The treatment should continue for 2 weeks after the first negative blood culture is obtained; however, if a metastatic focus of infection is noted, a prolonged therapy will be required.

Should the Catheter be Removed?

Catheters in which the insertion site is painful, erythematous, indurated, or with exudate; and tunneled catheters that manifest a tunnel infection should be removed as soon as possible [5]. For exit site infections not accompanied by gross purulence, systemic signs of infection, or positive blood cultures, treatment with local topical antimicrobial agents, as well
as systemic antibiotics can be tried based on culture data from a sample taken at the exit site. If treatment fails, then the catheter should be removed.

In the febrile patient who is clinically stable and without localizing signs of infection along the catheter insertion site, central catheters should not be removed until a microbiological assessment that includes samples of blood, with or without culture of insertion sites and hubs, is performed. Cultures that are positive from a single blood sample for organisms that are part of the normal skin flora, such as coagulase-negative staphylococci, diphtheroids, Micrococcus, or Propionobacterium spp., should be repeated to establish whether a true bloodstream infection is present [5,7]. If true bacteremia has been established, and there is no alternative source, catheters should be removed. Catheter-related infections due to coagulase staphylococci are a special case in that antibiotics alone without catheter removal are usually adequate to treat the acute infection [5]. However, recurrent infection is highly likely if the catheter is retained; unless there are cogent reasons for keeping the catheter in place, it should be removed [54]. If a catheter has been changed over a guide wire, and there is growth of ≥15 organisms from the tip of the removed catheter, the newly placed catheter is almost certainly infected and should be removed [3–5].

Catheter Salvage

In the case of long-term, tunneled, semipermanent catheters or ports that cannot be easily removed or for patients who have limited vascular access, treatment of catheter-associated infection with antibiotics without catheter removal can be tried. Catheter salvage is not recommended for patients with complications of catheter infection, such as suppurative phlebitis, endocarditis, tunnel infection, or for patients who have severe sepsis or have an implanted intravascular device, such as a prosthetic cardiac valve [5].

If salvage is considered, most success has occurred with coagulase-negative staphylococcal infections [5,7,54]. For bloodstream infections due to S. aureus and Candida spp., catheter salvage should be reserved for extenuating circumstances, i.e., when there is no alternative access. These infections and those due to gram-negative bacilli almost always require catheter removal [5]. Thrombolytics are not recommended as an adjunct to the treatment of catheter-associated bloodstream infection [38].

Antibiotic lock therapy, as an adjunct to systemic antimicrobial therapy, has been used for salvage of long-term catheters. In general, lock therapy involves the instillation of 2 to 5 mL of an antibiotic, often with an anticoagulant, into the catheter, allowing it to dwell until the catheter
is reaccessed [7]. Ethanol and EDTA have also been used for lock therapy [55–57]. Compatibility issues are important as some solutions may influence the integrity of the catheter structure. Short-term catheters are less likely to have an intraluminal source of infection and are less likely to benefit from antibiotic lock therapy. The lock therapy antimicrobial agents and systemic antibiotics should be used concomitantly. In general, the duration of lock and systemic therapy ranges from 7 to 14 days. If antibiotic lock therapy cannot be given, then systemic treatment should be administered directly through the infected catheter. If patients with no alternative access do not respond to the antibiotic treatment, exchange over a guidewire can be attempted [5].

For treatment of infections due to gram-positive cocci, an antibiotic lock solution containing a combination of vancomycin plus heparin or saline is used most often; the vancomycin instilled should be 1,000-fold higher than the MICs for the bacteria involved [7]. A small randomized placebo-controlled trial of antibiotic lock therapy using vancomycin or ceftazidime for gram-positive or gram-negative organisms, respectively, found a trend to successful outcome associated with lock therapy, and anecdotal reports of successful cure of infection with gentamicin, amikacin, ciprofloxacin, ampicillin, cefazolin, ceftazidime, and minocycline–EDTA, have been reported [5,58].
REFERENCES

Urinary tract infection (UTI) remains a common nosocomially acquired infection, accounting for approximately 25% to 40% of all infectious complications in hospitalized patients [1–4]. In a nation-wide surveillance study in the USA of nearly one half million intensive care unit (ICU) patients, UTI accounted for 23% of all infections and was associated with urinary catheters in 97% of patients [1]. Similar findings have recently been reported from surveys from Spain [2], Germany [3], and Brazil [4] with an overall incidence of urinary catheter-associated UTI of about 1 to 10 episodes per 1000 catheter days. Furthermore, the urinary tract is the most frequently recognized source of gram-negative bacteremia, which constitutes a major cause of infectious morbidity and mortality for the critically ill patient [5,6]. Approximately 100,000 annual admissions to acute care hospitals in the USA have been attributed to severe infections of the urinary tract [7]. Complicated UTI, progressive antimicrobial resistance, and the prevention of UTIs with the widespread use of indwelling urinary catheters remain major challenges for critical care practice.

THE PATHOPHYSIOLOGY OF UTIs

UTIs are primarily caused by gram-negative bacilli (71%) with gram-positive pathogens and fungi accounting for the remainder of microorganisms [5]. Escherichia coli is by far the most common cause of community-acquired and nosocomially acquired UTI. Most UTIs arise from ascending infection by enteric organisms that colonize the perineum and distal urethra. Specific clones of E. coli have evolved that readily colonize the uroepithelium and cause UTIs. These clones possess the requisite set of virulence genes needed to successfully attach, survive, and invade the urinary tract in nonimmunocompromised patients with anatomically normal genitourinary (GU) tracts [8].
An essential characteristic of uropathogenic *E. coli* is its ability to adhere to uroepithelial membranes. Urinary isolates of *E. coli* possess an array of adhesins including: type I (common pili), S pili, FIC pili, and P pili. These pili (also known as fimbria) are bacterial surface structures that facilitate attachment to epithelial surfaces. Type I pili bind to mannose-containing polysaccharides on the cell surface of epithelial membranes. This allows the organism to attach and persist within the urinary tract and avoid elimination during micturition [9].

Another important characteristic of uropathogenic *E. coli* is the expression of P pili on the bacteria’s outer membrane [10]. P pili bind to α-D-galactose 1 → 4 β-D-galactose (Gal–Gal) containing disaccharides of the globoseries of glycolipids found in blood group P antigens. These glycolipids are also found on the epithelial surfaces of the upper urinary tract and enterocytes. The ability of *E. coli* to express P pili is particularly important in the establishment of upper UTIs where Gal–Gal disaccharide-containing glycolipids are found in large concentration. Recent genetic analysis reveals that bacterial pathogens cluster their virulence factors in discreet loci along the chromosome known as pathogenicity associated islands (PAIs). These genetic elements contain a large number of genes associated with virulence and distinguish uropathogenic strains from nonpathogenic colonizing strains [8].

Other genera of the Enterobacteriaceae, including *Citrobacter*, *Klebsiella*, *Enterobacter*, *Serratia*, *Proteus*, *Morganella*, and *Providencia* spp., become more common causes of UTI when patients receive antibiotics or have anatomic or functional abnormalities in urine flow [11–13]. The microbiology of UTIs after short-term urinary catheterization is similar to that observed in the noncatheterized patient. However, long-term (>30 days) catheterization generates an environment that supports a complex and often polymicrobial microflora. An extensive extracellular array of microbial-derived polysaccharides surrounds bacterial microcolonies within the lumen of the long-term urinary catheter. This biofilm structure protects bacterial populations from immune, phagocytic, or antibacterial clearance [12]. Bacteria found in the urine of chronically catheterized patients differ from noncatheterized patients. *Proteus*, *Providencia*, *Morganella*, and *Pseudomonas* species become more common, whereas *E. coli* and *Klebsiella* species become less common (Fig. 80.1). *Proteus* species, some other gram-negative enteric organisms, and *Staphylococcus saprophyticus* synthesize the enzyme urease, a known bacterial virulence factor for the urinary tract. The generation of ammonia from the breakdown of urea increases regional pH, favoring the generation of the “triple-phosphate crystals” struvite and apatite in urine. Struvite crystals can block urinary catheter flow and promote the formation of urinary calculi [13].
Gram-positive bacteria occasionally cause UTIs in critically ill patients. The isolation of *Staphylococcus aureus* in the urine is significant as it often accompanies staphylococcal bacteremia. *S. aureus* isolation from urine cultures, particularly of noncatheterized patients, should prompt a search for extrarenal sources of staphylococcal infection. *S. aureus* may also colonize chronically catheterized patients. This is particularly true for methicillin-resistant *S. aureus* strains, which may thrive in hospital settings with many elderly, catheterized patients [1,2].

Enterococci are prevalent in the GU tract of elderly populations and among patients with long-term urinary catheters [11,12,14]. The remarkable ability of this organism to rapidly evolve resistance to antimicrobial agents, including β-lactam antibiotics, aminoglycosides, quinolones, and recently vancomycin, contributes to making this organism a frequent cause of health care associated infection [1,7]. It should be noted, however, that at least in premenopausal women with symptomatic UTI, poor correlations were found between voided and catheterized urine cultures when either enterococci or group B streptococci were detected [15]. In a recent study comparing urinary culture derived from midstream voiding urine with immediate straight catheterization of the bladder urine, the positive predictive value (likelihood that catheterized bladder urine would have enterococci present when it was found in voided midstream urine) of a positive culture for enterococci in voided urine was only 10% to 33% [15]. How
relevant this discrepancy is to determining the frequency of enterococcal UTI in critical care units remains unclear at present.

*Candida* species and other fungal organisms may colonize or infect the GU tract. Candiduria may be associated with hematogenous dissemination (“descending UTI”) or ascending UTIs from perineal surfaces. The unique problems associated with the isolation of *Candida* species of the urinary tract are considered in the final section of this chapter.
HOST DEFENSE MECHANISMS AGAINST UTI

The human GU tract is remarkably resistant to UTI by mechanical, mucosal, and immunologic mechanisms. The flushing action of urinary flow itself is an important defense against UTI. The frequent occurrence of UTIs after obstruction or incomplete bladder emptying attests to the importance of micturition in clearing potential pathogens. Patients with neurogenic bladder or vesicoureteral reflux are highly susceptible to UTI and renal scarring. While urinary pathogens must possess a full complement of virulence factors to cause infection in the anatomically normal urinary tract, UTI in the obstructed urinary tract occurs with bacterial species devoid of special urinary virulence factors [8].

Urinary osmolarity, urea concentration, pH, and oxygen concentration limit the growth potential of many bacterial pathogens in the urinary tract. Continuous sloughing of uroepithelial cells, urinary mucosal glycocalyx (slime), and secretion of the Tamm-Horsfall protein assist in the mechanical removal of adherent bacteria that have entered the urinary tract [14].

The mucosal surfaces of uroepithelial cells of patients vary in their ability to attach bacteria depending upon the nature of mucopolysaccharide content and its chemical composition. Patients with high concentrations of Gal–Gal disaccharides on the cell surfaces of the urinary tract are predisposed to UTI from P-piliated E. coli [8]. Patients who are nonsecretors of blood group antigens have an increased risk of UTI [9,10,16]. Blood group antigens coat uroepithelial cells when secreted onto the mucosal surface. These antigens prevent attachment of bacteria to adhesin-receptor oligosaccharides on the surface of epithelial cells. Individuals who fail to secrete blood group antigens are rendered infection prone to UTI.

Although secretory immunoglobulin, neutrophils, and cell-mediated immunity contribute to the host defense against UTI, their roles are secondary to mechanical and physical barriers to infection. Uroepithelial cells produce the chemokine interleukin-8 (IL-8) in response to E. coli infection. IL-8 promotes neutrophil migration to the urinary tract which reduces the risk of disseminated infection. Patients differ in their level of expression of the IL-8 receptor CXCR1. Decreased CXCR1 expression in the urinary tract might contribute to increased susceptibility to pyelonephritis in some patients [16].

Adult women are much more likely to develop UTI than men. Women are more likely to develop pyelonephritis if they are sexually active, use
spermicidal agents, experience urinary incontinence, have diabetes mellitus, or a family history of UTI [17]. The increased anatomic distance from the urethral orifice to the urinary bladder, the infrequent presence of gram-negative bacteria around the male urethra, and the production of inhibitory prostatic secretions protect men from UTI until they become elderly [18]. Bladder neck obstruction from age-related benign prostatic hypertrophy causes urinary obstruction and UTI in elderly men.

Asymptomatic bacteriuria is a commonplace occurrence for adult women, particularly elderly women, despite the absence of any recognized anatomic defect or immune deficiency. Our understanding of the role of asymptomatic bacteriuria in disease causation or recurrent symptomatic UTI has evolved significantly over the past few decades [19–21]. Epidemiologic studies now demonstrate that with exception of pregnancy, severe neutropenia, or diabetes mellitus in women or preceding urologic procedures in men, treatment of asymptomatic bacteriuria is not only ineffective, it may well do more harm than good [22]. Treatment alters the urinary and intestinal microbiome thereby increasing the risk of subsequent symptomatic UTI and promotes acquisition and infection by antibiotic-resistant uropathogens. Asymptomatic bacteriuria microorganisms might actually prevent infection of more pathogenic organisms, although this has yet to be definitively established. Unless specific indications exist, treatment of asymptomatic bacteriuria is discouraged in existing guidelines [20,23]. This recommendation holds true in the presence or absence of an indwelling urinary catheter.
Acute Pyelonephritis

Acute pyelonephritis can precipitate severe sepsis/septic shock when complicated by urinary obstruction, papillary necrosis, or other local suppurative complications. Failure of the patient to respond clinically within 72 hours to seemingly appropriate antimicrobial therapy should prompt a search for complications of UTI. Functional or mechanical obstruction to urinary flow is the principal underlying cause of treatment failure in UTI. Obstruction may arise from extrarenal causes such as retroperitoneal or pelvic masses or abnormalities intrinsic to the GU tract such as renal calculi or ureteral obstruction. Alleviation of obstruction facilitates antimicrobial treatment and is often essential to successfully eradicate infections in the upper urinary tract system [24].

Suppurative Complications of UTI

Abscess formation within the GU tract may take several forms and pose a diagnostic and therapeutic challenge. It is important to distinguish between these entities because the clinical implications and medical–surgical management of each process differs substantially (see Table 80.1). Radiographic findings in a typical case of emphysematous pyelonephritis (usually caused by enteric bacteria, not Clostridium spp. or other anaerobes) are seen in Figure 80.2 A,B. Suppurative complications of UTI necessitate urgent intervention with percutaneous or surgical drainage [24].

CT, computed tomography; UTI, urinary tract infection.
FIGURE 80.2 Radiographic findings in a diabetic woman with emphysematous pyelonephritis caused by Escherichia coli. A: Plain abdominal radiograph with evidence for gas in the left renal fossa. B: Computed tomography scan confirming gas in the left kidney. This patient recovered following emergency nephrectomy and antimicrobial therapy.

Diagnostic Methods for UTI

The clinical diagnosis of acute UTI of the upper urinary tract in the noncatheterized patient is usually straightforward, with a history of urinary frequency and dysuria accompanied with costovertebral angle (CVA) tenderness and signs of systemic toxicity. The urinalysis often shows positive “dipstick” results for leukocyte esterase and nitrite, markers for leukocytes and enteric bacteria. The presence of excess numbers of urinary leukocytes and bacteria in the urinary sediment, in the absence of contamination by epithelial cells, is indicative of a UTI in symptomatic patients.

The Gram stain of unspun urine is helpful for determining the most likely agent causing the UTI. Gram-negative rods in the urine are readily identifiable and this confirms the presence of significant bacteriuria. The finding of more than one organism per high-powered field in unspun urine equates with >10^5 colony-forming units (CFU) per mL [24]. Urinary Gram stain can also detect gram-positive microorganisms such as enterococci and staphylococci, and fungal elements. Polymicrobial bacteriuria is often apparent by urinary Gram stain and may be seen in UTI from long-standing urinary catheterization, entero-vesical fistula, or complicated UTI associated with obstruction or foreign bodies.
Patients with severe UTIs requiring critical care management should have quantitative urinary culture performed, preferably before the initiation of antimicrobial therapy. The urine culture confirms the diagnosis and defines the most appropriate antimicrobial agent for treatment. The progressive increase of antimicrobial resistance makes it imperative to carefully select antimicrobial agents based on susceptibility patterns of the infecting microorganism. Greater than $10^5$ CFU per mL in clean catch, mid-stream urine is generally diagnostic. The quantitative level of bacteriuria diagnostic for acute UTI varies depending on the clinical situation [24–27].

In clinical surveys of symptomatic women with UTI repeated isolation of as few as $>10^2$ pathogenic microorganisms per mL is diagnostic [15,25]. Catheterized patients may also have UTI with $<10^5$ CFU per mL. The presence of an indwelling urinary catheter may not allow ongoing replication of microorganisms in the urinary tract to achieve levels greater than $10^5$ CFU per mL. Moreover, urinary cultures from non-instrumented men are significant with as little as $10^3$ CFU per mL [28]. The absence of pyuria and significant bacteriuria does not exclude the possibility of a potentially serious UTI. Patients with severe neutropenia may not have significant levels of pyuria. Urine cultures may be negative in more than 40% of patients with perinephric abscess, and most patients with renal cortical abscesses have urinalyses without significant bacteriuria [29]. Complete unilateral urinary obstruction associated with pyonephrosis can fail to show the primary pathogen within voided urine. Urinary stent placement increases the risk of UTI. In a recent survey voided urine specimens taken at the time of stent removal were negative in the presence of microbial colonization in 40% of the patients [30].

Blood cultures should be obtained for all patients who are septic in the setting of a UTI. Urine cultures should also be performed from nephrostomy tube drainage in patients with prior urinary diversion procedures. It is generally unnecessary to change a urinary catheter before the acquisition of urine cultures in patients with acute symptomatic UTI.
Complicated UTIs often require radiologic methods to establish the correct diagnosis. Routine abdominal radiographs may assist in the diagnosis of complicated forms of UTI. The presence of radiopaque renal calculi can be readily detected on abdominal radiography. Emphysematous pyelonephritis appears as an abnormal collection of gas within the renal parenchyma. Gas is detectable in the urinary collecting system in many patients with pyonephrosis. Abnormal renal shadows and loss of psoas margins may suggest the presence of a perinephric abscess. Renal ultrasonography and computed tomography (CT) have replaced the intravenous pyelogram (or excretory urogram) as the principal radiographic technique in the detection of complicated UTI. The anatomic definition of the kidney and perirenal tissues is superior with a contrast-enhanced abdominal CT scan and is generally the preferred imaging method for complicated UTI (see Table 80.1). Renal ultrasound provides another rapid method of detecting hydronephrosis and anatomic detail of the renal parenchyma. Ultrasonography can also determine the solid or cystic nature of a renal mass detected on abdominal CT. Ultrasound can image the kidney on any plane and may be performed urgently in the absence of intravenous contrast media. The CT scan or renal ultrasound is indispensable for the localization of inflammatory processes during diagnostic aspiration or percutaneous drainage procedures. Magnetic resonance imaging (MRI) provides detailed information about the renal structures and retroperitoneal space, but the CT has sufficient resolving power for most forms of renal inflammatory disease.

The gallium-67–scan or indium-111–labeled leukocyte studies can occasionally be useful in the diagnosis of complicated UTI. These nuclear medicine studies assist in the differentiation between a renal neoplasm and a focal inflammatory process of the kidney. These studies are useful for the evaluation of patients with fever of unknown origin secondary to perinephric abscess or renal cortical abscess [31].
Patients admitted to the intensive care unit for management of UTI usually suffer from severe infections complicated by a systemic inflammatory response (sepsis) or suppurative complications of the GU tract. Medical management initially consists of stabilization of the patient’s hemodynamic parameters and supportive measures in the management of septic shock. After the completion of appropriate diagnostic studies, empiric antimicrobial therapy should be directed toward the most likely infecting urinary pathogen(s). A urinary Gram stain usually provides evidence of either a gram-negative or gram-positive bacterial pathogen. If this is unavailable or nondiagnostic, then broad-spectrum, empiric antimicrobial therapy is indicated.

For the septic patient presenting with septic shock from a UTI, the initial use of a β-lactam antibiotic (assuming there is no history of allergic reactions to β-lactams) in combination with an aminoglycoside or a fluoroquinolone have been the traditional therapeutic regimens for hospitalized patients. The β-lactam–aminoglycoside combination supplies optimal therapy for systemic infections with enteric gram-negative bacilli, enterococci, and nonfermentative, multiresistant, gram-negative bacterial pathogens. Severely ill septic patients who are immunocompromised also warrant combination antimicrobial therapy [32]. Increasingly, the therapeutic trend in empiric therapy is away from aminoglycosides to monotherapy with β-lactams alone, β-lactam–β-lactamase inhibitors, and/or fluoroquinolones [33].

Community-acquired UTIs of nonimmunocompromised patients who have not received antimicrobial agents infrequently harbor multiresistant gram-negative bacilli or *Pseudomonas* sp. Should the urinary Gram stain exclude enterococci as a potential pathogen, then single therapy with a third-generation cephalosporin, extended-spectrum penicillin, carbapenem (e.g., imipenem or meropenem), β-lactam–β-lactamase inhibitor (e.g., piperacillin–tazobactam) trimethoprim–sulfamethoxazole, or a fluoroquinolone is acceptable therapy while awaiting culture results. Local susceptibility patterns of urinary pathogens should guide the selection of antimicrobial therapy until specific susceptibility data are available. There is no evidence that combination antimicrobial therapy is necessary for UTIs caused by gram-negative bacilli unless *Pseudomonas aeruginosa* infection with neutropenia is present. A single antimicrobial agent known to be active against the infecting uropathogen should be employed once the causative organism is known. Parenteral therapy is generally administered until the patient has been rendered nontoxic and afebrile for 24 to 48 hours.
Therapy may then be administered orally and should be given for a total of approximately 2 weeks [32,33]. Patients with obstructive lesions and complicated UTIs not amenable to corrective surgery may require prolonged courses of antimicrobial therapy as indicated by their underlying urologic disorder.

Treatment options to treat UTIs have become much more complicated recently as a result of increasing prevalence of antimicrobial resistance among both hospital-acquired and community-acquired uropathogens. Fortunately, at least some new antimicrobial agents have entered the market recently to treat severe UTI from multidrug resistant (MDR) pathogens. Both of these new agents are $\beta$-lactam–$\beta$-lactamase inhibitor combinations: ceftolozane–tazoabactam [34] and ceftazidime–avibactam [35]. Both these combination drugs are now available and are specifically indicated to treat UTIs in patients requiring intravenous antibiotic therapy caused by MDR gram-negative bacteria. Common antimicrobial agents useful for the treatment of severe UTIs and their relative merits are listed in Table 80.2.

</table>
Adult dosing in patients with normal renal function; follow susceptibility test results and treat parenterally until systemic toxicity resolves.

Gentamicin or other aminoglycosides often given with a β-lactam agent in gram-negative septic shock or severe enterococcal infections.

Aztreonam dose can be increased to 2 g q8h for P. aeruginosa infection.

Piperacillin/tazobactam dose can be increased to 4.5 g q8h for P. aeruginosa infection.

MRSA, Methicillin-resistant S. aureus; UTI, Urinary tract infections; VRE, vancomycin-resistant enterococci; MDR, Multidrug resistant; ESBL, extended spectrum β-lactamase; KPC, Klebsiella pneumoniae carbapenemase; NDM, New Delhi metallo-β-lactamase.

Standard therapy for severe enterococcal UTIs has been ampicillin and an aminoglycoside. Although this regimen remains active against most enterococcal isolates, progressive antimicrobial resistance to aminoglycosides, ampicillin, and other β lactams and vancomycin has complicated the antimicrobial therapy for enterococcal infections [36]. Rare strains of β-lactamase–producing enterococci are susceptible to β-lactam inhibitors such as ampicillin/subactam or piperacillin/tazobactam. High-level aminoglycoside-resistant strains of enterococci are problematic, as the addition of an aminoglycoside no longer contributes to synergistic clearance of these infections. Aminoglycosides should not be used in this situation.

Glycopeptide-resistant strains of enterococci pose a serious threat to the antimicrobial management of enterococcal infections. Some of these isolates remain susceptible to β-lactam agents. Newer fluoroquinolones occasionally have activity against enterococci and may be useful in the treatment of glycopeptide- and β-lactam–resistant strains of enterococci. Tetracyclines and nitrofurantoin are useful alternatives for uncomplicated, enterococcal UTI if susceptibility testing indicates activity. Linezolid, an oxazolidinone that inhibits the initiation of translation at the 30S ribosome of bacteria, has activity against vancomycin-resistant enterococci [37]. Multidrug resistant enterococci are an infection control hazard in the ICU and contact precautions are recommended.

Antistaphylococcal penicillins such as nafcillin or oxacillin are indicated for the empiric therapy of renal cortical abscesses (renal carbuncle). Vancomycin should be instituted if there is a suspicion of the presence of methicillin-resistant staphylococcal isolates in a patient with a cortical abscess or perinephric abscess.

Urgent percutaneous nephrotomy tube placement for urinary drainage and abscess management is indicated for severely septic patients with
obstructed urinary collecting systems. Percutaneous catheter drainage of perinephric abscesses, renal carbuncles, and infected urinary cysts are often necessary in combination with antimicrobial therapy to manage these complicated UTIs. Open surgical drainage is reserved for patients who fail to respond to attempted percutaneous drainage.
PREVENTIVE MEASURES AGAINST UTI IN THE ICU SETTING

The most efficacious method of preventing UTIs among critically ill patients is not using urinary catheters at all or limiting their duration of use as much as possible [27,38]. Asymptomatic bacteriuria should generally not be treated whether an indwelling urinary catheter is present or not. Asymptomatic bacteriuria among pregnant women and severely immunocompromised patients should be treated with specific antimicrobial agents as the risk of ascending UTI in such patients is considerable and can be avoided by early medical intervention [39,40].

The Management of Catheter-Related UTI

The ubiquitous presence of the indwelling urinary catheter among hospitalized patients provides microbial pathogens ready access to the urinary tract with subsequent development of UTI. It is estimated that 10% of all hospitalized patients in the USA will have a urinary catheter inserted during their hospitalization, resulting in over 1 million UTIs and 40% of all hospital-acquired infection per year [27]. The overall incidence of catheter-acquired UTI among patients within critical care units varies from 0.5 to 10 UTI per 1,000 catheter days [27,40]. The risk factors for acquisition of catheter-related UTI include duration of catheter placement, increasing patient age, female gender, severity of underlying illness, and perhaps obesity [40,41]. The estimated risk of bacteriuria after urinary tract catheterization is approximately 5% for each day of catheterization. Chronically catheterized (more than 30 days) patients almost invariably have bacteriuria, and their admission to the ICU poses a threat of cross-contamination of urinary pathogens to other ICU patients. Despite continued infection control efforts to decrease the frequency of contamination, UTI remains the major complication of urinary catheters. The average, calculated, incremental cost associated with the hospital care of a patient with a catheter related UTI is $589.00 [38,42].

Pathogenesis

The catheter itself interferes with physiological host defense mechanisms against UTI. Trauma produced by an indwelling catheter may damage the bladder mucosa and the mucous layer that coats uroepithelial cells [27]. This exposes the cell surface of epithelial cells to bacterial adhesions and
increases the risk of UTI. Indwelling catheters prevent complete bladder emptying. Residual urine serves as a culture medium for bacteria in an inadequately drained urinary bladder. Additionally, temporary obstruction of urine flow caused by kinking or clamping of the urinary catheter can lead to bladder distension, vesicoureteral reflux, and infection.

Bacteria gain access to the urinary tract of catheterized patients by one of three mechanisms: (1) during insertion, (2) along the external surface after insertion, or (3) via the inner lumen of the urinary catheter. Implantation of bacteria into the bladder during catheter placement occurs at a frequency of approximately 0.5% to 8% [27]. This risk varies with the experience of the health care worker placing the catheter and with the level of periurethral colonization by potential uropathogens. Ascending infection from within the lumen accounts for approximately 20% of catheter-related UTIs [24]. The use of sterile, closed urinary collecting devices with a sterile vent to avoid a standing column of urine from the bladder to the collecting bag has decreased the frequency of UTIs. Optimal catheter design includes a sterile sampling port that obviates the need to open the system to collect urine samples. The collecting bag should have a large reservoir with a device to measure urine output with minimal manipulation of the catheter system.

Most catheter-related UTIs are derived from microorganisms that enter the urinary bladder along the external surface of the catheter [27,43]. The periurethral space becomes colonized with enteric organisms, which then migrate along the periurethral mucous sheath that surrounds the surface of the catheter. Continued movement of the catheter in and out of the urinary bladder occurs upon repositioning of the patient or catheter manipulations. This process provides ample opportunity for organisms coating the catheter surface to gain access to the urinary bladder and cause infection.

Numerous enteric organisms avidly adhere to the mucosal surface of the urinary bladder. Some organisms, such as Providencia stuartii and P. aeruginosa, also possess surface adhesins that bind directly to the urinary catheter itself. The urinary catheter becomes an ecologic niche for these organisms, resulting in prolonged infections that may persist for months in the catheterized patient [44]. Over 90% of P. stuartii bacteremias occur as the result of urinary catheter-induced UTIs [45]. The urease produced by Proteus species affects the local pH surrounding the catheter, which facilitates the deposition of struvite microcrystals on the surface of the catheter. These encrustations serve as a nidus for persistent colonization with urinary pathogens. Adherent bacteria establish microcolonies coated with extracellular polysaccharides. The continued buildup of this biofilm within the lumen of the urinary catheter eventually leads to obstruction of urinary flow [12,46]. The presence of a
foreign body within the urinary bladder interferes with the penetration and antimicrobial action of antibiotics. Bactericidal agents inhibit, but often fail to kill, microorganisms that adhere to catheter materials. Furthermore, the catheter serves as a foreign body inducing early degranulation and loss of bactericidal activity of neutrophils. These factors contribute to the difficulties eradicating urinary pathogens in the catheterized patient.

**Diagnosis**

The presence of bacteriuria in the catheterized patient documents colonization of the urinary tract but does not necessarily confirm the presence of an actual UTI. A UTI develops when a host response occurs to the presence of microbial pathogens in the urine. As many as 70% of patients who develop catheter-related bacteriuria remain symptom free and resolve spontaneously with the catheter removal [47]. It is generally acknowledged that the treatment of asymptomatic bacteriuria in the catheterized patient is not warranted, except in some specific circumstances [20,27]. The severely neutropenic patient with asymptomatic bacteriuria should be treated because of the risk of systemic infection in this patient population.

It is often difficult to recognize that a symptomatic UTI is present in the catheterized patient. Altered levels of consciousness may interfere with the patient’s awareness of the UTI. Furthermore, the presence of a urinary catheter removes the symptoms of urinary frequency and the perception of dysuria. Hematuria and pyuria may be found in the catheterized patient in the absence of urinary colonization with bacteria. Isolated pyuria in patients with asymptomatic bacteriuria is not an indication for antimicrobial treatment [20]. This is presumably related to sterile inflammation and trauma induced by the catheter itself. High-grade pyuria with fever supports the diagnosis of a UTI in the catheterized patient [48].

The presence of lower numbers of bacteria than the traditional \(>10^5\) CFU per mL can indicate infection in catheterized patients [49]. Quantitative counts as low as \(10^2\) CFU per mL may be significant in the catheterized patient. Low colony counts in catheterized urine can progress to high-grade bacteriuria in catheterized patients. Clinical laboratories should isolate and characterize urinary isolates from catheterized patients with low grade bacteriuria. A recent consensus review recommended the cutoff of \(>10^3\) CFU per mL for significant
bacteriuria in catheterized patients [48]. The high flow rate of catheterized urine, presence of inhibitors to bacterial growth, and significance of slow-growing organisms such as enterococci and Candida make it incumbent on the laboratory to characterize even low numbers of uropathogens in these patients. Moreover, polymicrobial bacteriuria occurs in more than 15% of patients with catheter-related UTI [49]. Multiple organisms obtained from a recently inserted urinary catheter (<72 hours) should be isolated, characterized, and subjected to susceptibility testing to ensure adequate treatment of catheter-related UTIs.

Most patients with catheter-associated UTIs have lower urinary tract involvement. Upper tract involvement occurs in up to one third of catheter-related UTIs and may have serious consequences [50]. The clinical and laboratory recognition of upper urinary tract involvement in persons with UTI (with or without a catheter) remains imprecise and unsatisfactory. ICU patients with UTIs may have altered levels of consciousness and may not be able to relate the symptoms of upper tract involvement. Radiographic indicators of upper tract involvement by ultrasound and CT include enlarged kidneys and focal nephritis; these are reliable diagnostic techniques in ICU patients. Evidence of systemic toxicity from a UTI is highly indicative of upper tract disease and should be treated accordingly. Bacteria confined to the urinary bladder, in contrast, readily clear with removal of the catheter and a short course of antimicrobial therapy, if necessary.

**Treatment**

The most important therapeutic modality in catheter-related UTIs is the removal of the urinary catheter itself. Up to two-thirds of patients with asymptomatic bacteriuria associated with urinary catheterization spontaneously resolve within 1 week after catheter removal [20]. Persistent bacteriuria longer than 48 hours after catheter removal should be treated with a short course (3 days) of an appropriate antimicrobial agent. If patients have persistent bacteriuria after short-course therapy, upper tract infection is assumed to be present and a 14-day course of an active antimicrobial agent is indicated [27,48].

If a patient becomes systemically ill from a UTI, treatment is warranted even if the catheter must remain in place. It is possible to successfully treat UTIs in patients with indwelling catheters, although treatment failures and reinfection occur at a greater frequency than in noncatheterized patients [24]. Antimicrobial agents useful in the treatment of catheter-related UTI are described in Table 80.2.

Routine replacement of indwelling urinary catheters complicated by UTI is generally unnecessary. Nonetheless, some organisms such as
Proteus, Providencia, Morganella, and Pseudomonas species and enterococci may colonize the urinary catheter in greater quantities than the bladder itself. Despite the fact that the microbiology of urine samples from indwelling catheters and replacement catheters does not differ markedly in the presence of a UTI, indwelling catheters should be replaced and urine cultures obtained if they malfunction, leak, or have been in place for prolonged periods (longer than 2 weeks) as a guide to antibiotic therapy for catheter-related infections. Leaking urinary catheters generally indicate luminal obstruction and require replacement.

Long-term urinary catheterization may be associated with other local suppurative complications, particularly in adult men. These include prostatitis, prostatic abscess, epididymitis, scrotal abscess, and other urethral complications. These local complications require urologic management and necessitate the removal of the urethral catheter.

**Prevention**

**Alternatives to Urethral Catheterization**

The high frequency of catheter-related UTIs has led to concerted efforts to find alternative methods to manage the incontinent patient and patients with urinary outflow obstruction. Bladder training, meticulous nursing care, special linens, and adult diapers may assist some incontinent patients and avoid long-term catheterization.

Condom catheterization has been used for men with urinary incontinence and consists of the application of an external collector about the penis with a collection tube and drainage bag. Condom catheterization may be a reasonable alternative in highly motivated, cooperative, selected patients. However, leakage of the catheter, kinking and disruption of the collecting system, and maceration and ulceration of the epithelium of the penis are frequent complications of condom drainage. Regrettably, the overall incidence of UTIs with condom drainage does not differ significantly from indwelling catheter drainage.

**Catheter Design, Maintenance, and Care**

Because most catheter-related infections are derived from endogenous perineal organisms adherent to the exterior surface of the catheter itself, daily application of antimicrobial materials at the urethral orifice would seem to be a logical preventive measure. However, randomized, controlled, clinical trials with mental care and application of povidone-iodine solution or topical polyantimicrobial applications have failed to convincingly demonstrate a reduction in catheter-related infections.
This procedure cannot be recommended as a means of prevention of catheter-associated UTI.

Considerable effort is under way to develop a urinary catheter that prevents binding with bacteria, inhibits biofilm formation, or possesses antibacterial properties. Existing studies and a recent evidence-based systematic review of the existing literature indicates that antibiotic-coated catheters reduce the incidence of asymptomatic bacteriuria following short-term catheterization; however, there is no clear evidence of reduced symptomatic UTI or major complications such as bacteremia [54–56]. Such catheters may be considered for selected patients at great risk of complications for UTI such as a patient with severe neutropenia, but such patients are uncommon in most critical care units.

Exogenous contamination of urine within the collection bag remains a potential problem associated with indwelling urethral catheters. The instillation of antiseptic agents within the drainage bag as a means of prevention of catheter-related UTIs has met with conflicting results [55,56] and this infection control strategy for UTI is not recommended based upon current clinical evidence [27,57,58]. The urinary collection bag should not be allowed to be elevated above the urinary bladder. This results in reflux of voided urine back into the bladder with its attendant risk of inducing UTI. Collecting bags with antireflux valves should be used to avoid this complication of urinary catheterization.

Short-term systemic antimicrobial prophylaxis against catheter-related UTI might be useful in special circumstances such as renal transplantation or foreign body implant surgery. A summary of evidence to support prevention and treatment recommendations for urinary catheter-associated UTI is listed in Table 80.3.

associated UTI to warrant the use of antibiotic therapy.

• The clinical value and cost-effectiveness from the use of antimicrobial-coated urinary catheters to prevent catheter-associated urinary tract or other complications (e.g., bacteremia, sepsis, or suppurative lesions) remains unclear [54–56].

• There are insufficient data to support the use of chemical disinfection, cranberry product antiseptics, or locally applied antibiotics within the urinary drainage system as a means of preventing catheter-associated UTIs [57,58].

• Daily meatal care to prevent contamination of the external surface of the urinary catheter is not recommended as a means of preventing catheter-associated UTIs [43].

• Persistent bacteriuria >48 hours after removal of a urinary catheter should be treated with antimicrobial agents [27].

Summary of recommendations in the management of candiduria in the ICU patient

• Quantitative cultures with >10^3 CFU/mL of Candida spp in a catheterized patient or >10^4 CFU/mL of Candida spp in a noncatheterized patient is considered clinically significant [48,67].

• The finding of a fungus ball within the urinary collecting system, papillary necrosis, fungal casts in the urine, or renal abscess in the presence of candiduria is considered clinically significant [48,68,70].

• In medically stable patients without major immunocompromised states, simple removal of an indwelling urinary catheter without specific antifungal therapy may be an acceptable treatment option [48,60,61].

• Because of high levels of urinary excretion, fluconazole is generally preferred over caspofungin, other β-glucan inhibitors, and other triazoles (such as voriconzole, itraconazole, or posaconzole) in the treatment of genitourinary candidiasis [48,70].

• Bladder irrigation with a short course of amphotericin B (2 days) remains a viable treatment option in catheterized patients with candiduria in the absence of evidence of disseminated candidiasis [72].

• A short course of fluconazole (5–7 days) is usually sufficient to treat UTIs due to Candida spp. [75,76].

UTI, urinary tract infections; CFU, colony-forming units.
THE PROBLEM OF CANDIDURIA

The clinical interpretation of the isolation of *Candida* species from the urine is problematic in that candiduria may occur in a spectrum of illnesses ranging from simple urinary contamination to life-threatening systemic candidiasis. *Candida* species are normal inhabitants of the vaginal tract of women and may contaminate inadequately collected urine specimens. This is particularly true for older women, diabetics, and patients receiving antibacterial therapy. Additionally, *Candida* species frequently colonize the urinary tract of catheterized patients. These organisms are of marginal clinical significance and frequently disappear on removal of the urinary catheter without any specific antifungal therapy [59]. In a detailed survey of 861 patients with funguria by the national mycoses study group, no treatment was given in 155 patients and funguria resolved spontaneously in 76% of these patients [60]. Even for ICU patients, simply changing an indwelling catheter with a new one will spontaneously clear candiduria in 20 to 40% of cases [61].

However, tissue invasive infection of the urinary bladder has been documented cystoscopically for patients with GU candidiasis. *Candida* cystitis may produce a friable white pseudomembrane on the bladder mucosa similar to the findings of oral thrush. Furthermore, ascending urinary infection of the kidney and renal pelvis may follow GU candidiasis. Papillary necrosis, fungus ball formation, urinary obstruction, bladder rupture, and perinephric abscess have all been described from ascending infection with *Candida* species [62,63]. *Candida* infection of the upper urinary tract may arise from hematogenous dissemination of *Candida* organisms from extrarenal sites. Microabscesses of the renal parenchyma with subsequent candiduria are frequently present among those with disseminated candidiasis. A positive urine culture for *Candida* species may be the first indication of disseminated candidiasis for the critically ill patient. Therefore, the clinical significance of *Candida* in the urine remains a diagnostic dilemma.

Quantitative culture of the urine has been used in an attempt to determine the clinical ramifications of candiduria. Unfortunately, the quantitative colony counts of *Candida* species in the urine do not have the same diagnostic and prognostic implications as quantitative bacteriology of the urine [48,63]. Large studies and review of this topic [48,64,65] indicate that quantitative values for candiduria of clinical significance are seen at more than $10^3$ CFU per mL (catheterized patients) or more than $10^4$ CFU per mL (noncatheterized patients). The finding of urinary casts made up of *Candida* elements is of diagnostic
significance and indicates invasive upper tract candidiasis. Candiduria associated with a fungus ball in the urinary collecting system dictates the need for antifungal therapy, as does papillary necrosis or abscess formation within the renal parenchyma. Recurrent isolation of *Candida* species from urine cultures of immunocompromised patients, or patients with unexplained fever and pyuria, suggests UTI with *Candida* species. Evidence of concomitant infection with *Candida* organisms in other organ systems increases the likelihood of the significance of *Candida* isolates in the urine. Disseminated candidiasis should be considered for patients with repeated and unexplained *Candida* isolates in the urinary tract [66–68]. Biomarker plasma sample evidence of disseminated candidemia such as an elevated β-D-glucan level can assist in early detection of systemic candidiasis in septic patients [32].
THE TREATMENT OF GU CANDIDIASIS

There are several management options available for candiduria, depending on the clinical circumstances of each patient. The discontinuation of antibacterial agents, removal of immunosuppression, or removal of urinary catheters may be sufficient to spontaneously clear candiduria in medically stable patients [69].

Published treatment guidelines for GU candidiasis recommend fluconazole in place of amphotericin B as the preferred treatment in the ICU setting [61,70]. This triazole compound is water soluble, available as oral or intravenous formulations, and is excreted as the active compound in the urine. Posaconazole, itraconazole, caspofungin, and voriconazole might be useful despite the fact that they are excreted by the kidney and do not uniformly achieve fungicidal levels in the urine. Tissue levels in the upper urinary tract might still be sufficient to treat genitourinary candidiasis for selected patients, but clinical experience is limited [61]. Fluconazole also provides systemic antifungal activity when unrecognized disseminated candidiasis is present.

It is now recommended that antifungal susceptibility testing be performed for serious Candida infections for fluconazole, itraconazole, and flucytosine [71]. Resistance among Candida albicans isolates is increasingly recognized and these findings emphasize the necessity of antifungal susceptibility testing [72]. Candida krusei is intrinsically resistant to fluconazole; Candida lusitaniae is resistant to amphotericin B; and Candida glabrata is variably sensitive to azole antifungal agents. C. parapsilosis appears to be less susceptible to the echinocandins although the clinical significance of this finding is debatable [70]. Amphotericin B in vitro susceptibility testing is technically difficult and the methodology has not yet been standardized for routine clinical laboratory testing [71]. High doses of amphotericin B instilled into the bladder is potentially toxic to uroepithelial cells; however, a 2-day infusion of 50 mg of amphotericin B in 1,000 cc of sterile water per day is effective [72]; a single systemic dose of amphotericin B can also clear candiduria [73]. Systemic fluconazole or amphotericin B is indicated in candiduria patients with suspected systemic candidiasis, renal abscess formation, and fungus balls within the urinary collecting system [74]. Candida UTI may be readily treated with oral or intravenous fluconazole. A short course of fluconazole at 200 mg orally followed by 100 mg daily for 5 to 7 days is generally sufficient for the treatment of Candida [75] cystitis while upper urinary tract disease is generally treated with 200 to 400 mg fluconazole for 2 weeks [76]. Clinical evidence in support of the current management strategies for GU candidiasis is provided in Table
Utility of Ultrasonography for Diagnosis of UTI

Ultrasonography is an important imaging modality for diagnosis of UTI, particularly if there may be a complication such as obstructive uropathy, perinephric abscess, kidney stone, or emphysematous pyelonephritis. As it can be performed rapidly at point of care, ultrasonography is the first line imaging technique where there is clinical suspicion of complicated UTI. Equipment and scanning technique for ultrasonography of the kidney and bladder are reviewed elsewhere in this textbook (Chapter 200, Acute Kidney Injury).

Characteristic Ultrasonography Findings

Uncomplicated pyelonephritis results in enlargement of the kidney but otherwise has no specific findings. Normal kidney length is 9 to 12 cm. Hydronephrosis is readily detected with ultrasonography (Video 80.1). When associated with clinical evidence of UTI, its presence mandates consideration of decompression of the infected space. Perinephric abscess results in a heterogeneous crescent-shaped collection that surrounds the kidney, while renal abscess appears as a complex hypoechoic mass with irregular thick walls. Kidney stones may complicate a kidney infection; they are identified as strongly hyperechoic structures within the kidney with associated acoustic shadowing. Emphysematous pyelonephritis results in hyperechoic foci within the parenchymal/pelvocalyceal area with associated comet tail artifact or mild acoustic shadowing. Bladder infection has no characteristic features on ultrasonography examination.

1150, 1990.

The central nervous system (CNS) infections of major interest in the intensive care unit (ICU) are bacterial meningitis, encephalitis, brain abscess, and other parameningeal foci of infection. The clinical presentations of these diseases may overlap. Meningitis means inflammation of the leptomeninges; its hallmark is stiff neck. Encephalitis is a syndrome consisting of disturbance of cerebral function and inflammation of the brain parenchyma, usually associated with cerebrospinal fluid (CSF) pleocytosis. Many cases of bacterial meningitis also fit this definition of encephalitis due to the occurrence of mental status changes, seizures, or coma. Focal infections, such as brain abscesses, may present more as space-occupying lesions than with classical infectious signs or symptoms.

CSF examination is the major tool used for the diagnosis of CNS infections. The terms purulent and aseptic describe contrasting CSF formulas, though overlap exists. The typical purulent CSF has a white blood cell count of more than 1,000 cells per μL (most of which are neutrophils), a depressed glucose concentration (<40 mg per dL), and an elevated protein level (>100 mg per dL); it is most commonly seen in bacterial meningitis. In contrast, an “aseptic” formula has a lower total leukocyte count with a predominance of mononuclear cells, a glucose concentration greater than 40% to 50% of the blood level, and less marked elevation of protein; this picture characterizes most other CNS infections. An intermediate CSF formula, in which a moderate lymphocytic pleocytosis is accompanied by depressed glucose and elevated protein, suggests granulomatous disease.
Initial evaluation of the patient with suspected CNS infection should focus on defining the nature of the symptoms (meningitic vs. encephalitic) and the presence and pattern of neurologic involvement (focal vs. diffuse).

If bacterial meningitis is suspected, expeditious analysis of CSF is critical. This must be balanced with the need to administer antibiotics promptly; delays as short as 3 hours have been shown to lead to unfavorable outcomes [1,2]. If lumbar puncture (LP) is delayed, antibiotics (and dexamethasone; see later) should be started as soon as blood cultures have been obtained while efforts to obtain CSF proceed [3].

LP is not without risk. In patients with bleeding disorders, it should be delayed until the defect(s) can be corrected [4]. LP may be hazardous in the settings of intracranial mass lesion. Concern for cerebral herniation as a consequence of the procedure has led to the common practice of routinely performing computed tomography (CT) scanning prior to LP. This practice is not well founded, however [5]. A prospective study confirmed that CT scans rarely discover abnormalities that would represent a contraindication to LP except among patients who have a prior history of CNS disease, immunosuppressive disorders, seizures, moderate-to-severe impairment of consciousness, papilledema, or focal neurological findings [6].
BACTERIAL MENINGITIS

Bacterial meningitis is perhaps the most clear-cut emergency in the field of infectious diseases. Delayed or inadequate treatment increases the risk of death or significant neurological impairment [1].

Etiology

The predominant organisms vary based on the age and underlying condition of the host. Historically, bacterial meningitis in the United States has been primarily caused by five organisms: *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Listeria monocytogenes*, *Haemophilus influenzae*, and group B streptococcus. However, immunization of young children against *H. influenzae* and *S. pneumoniae* has had a marked impact, raising the average age of meningitis from 15 months old to 42 years old [7].

*S. pneumoniae* accounts for more than half of all community-acquired bacterial meningitis cases in the United States after the neonatal period [7,8]. The case fatality rate is 20% to 30% in adults and survivors have approximately a 30% risk of sequelae [9,10]. Pneumococcal meningitis is more common in the setting of a CSF leak, hypogammaglobulinemia, asplenia, alcoholism, head trauma, or cochlear implant [11]. Routine infant immunization has also reduced the incidence of pneumococcal meningitis in older children and adults due to a reduction in *S. pneumoniae* carriage in the younger population [12,13], though there has been an increase in pneumococcal meningitis caused by nonvaccine strains [14].

*N. meningitidis* incidence has declined substantially in recent years, but still causes more than 10% of bacterial meningitis in the United States [7,15]. Incidence peaks in three age groups: infants and children under 5 years, adolescents/young adults (16 to 21 years), and adults over 65 years [16]. It is the one form of bacterial meningitis associated with epidemic spread, though the majority of cases in the United States are sporadic [9,16]. Routine immunization with a meningococcal conjugate vaccine directed against serogroups A, C, W, and Y is currently recommended for preadolescents, freshman entering college, and military recruits as well as special populations at increased risk of meningococcal disease [16]. Vaccines providing protection from serogroup B have recently been licensed and are currently recommended for individuals over 10 years of age at increased risk [17]. To date, there does not appear to have been replacement with nonvaccine meningococcal serotypes in the United States [18].
*L. monocytogenes* is a common cause of meningitis in the neonatal period or in the setting of malignancy, immunosuppression, or alcoholism. Approximately 30% of patients have no apparent immunocompromising condition; most of these individuals are older than 50 years [7,19]. Listeria may be associated with lower CSF WBC counts and higher CSF glucose than other bacterial meningitides [9,20].

*H. influenzae* type B was formerly the most common cause of bacterial meningitis among young children. Childhood vaccination has reduced the incidence of invasive *H. influenzae* type B disease by more than 90% [7,9,21]. Sporadic cases have been reported in unimmunized and partially immunized children and *H. influenzae* strains not covered by the vaccine can also cause meningitis [22]. *H. influenzae* in adults is uncommon and is usually associated with predisposing factors, particularly defects in humoral immunity [21].

Gram-negative bacillary meningitis occurs in the neonatal period or after neurosurgery or trauma [7,23]. Craniotomy is associated with a 1% to 2% rate of bacterial meningitis [24]. Increased infection rates are associated with perioperative steroids, CSF leak, and ventricular drainage [25]. Spontaneous gram-negative bacillary meningitis is associated with advanced age, cancer, and bacteremic urinary tract infection; *Escherichia coli* and *Pseudomonas* sp. are the most frequent pathogens [23].

*Staphylococcus aureus* meningitis is associated with neurosurgery or trauma. Community-acquired cases occur in the presence of a focus of infection outside the CNS, such as endocarditis or soft tissue infections, and have a worse prognosis [26]. Meningitis in patients with CSF shunts or other hardware such as Omaya reservoirs and deep brain stimulators is most commonly caused by skin flora (*S. aureus, Staphylococcus epidermidis, and Propionibacterium acnes*) and Gram-negative bacilli [27–30]. These infections can have an indolent presentation and milder CSF abnormalities [3,24,28]. Use of shunt catheters impregnated with antimicrobials reduces the rates of infection [31].

Several additional species of streptococci can cause meningitis. Group B streptococcus, *Streptococcus agalactiae*, is the most common cause of neonatal meningitis, though rates of early-onset disease have decreased with use of intrapartum penicillin prophylaxis [7,9]. Rates of group B streptococcal invasive disease in adults are increasing, particularly in diabetic patients, but only a small proportion present as meningitis [32]. *Streptococcus suis* is an increasingly common cause of meningitis in Asia and should be considered in travelers who may have ingested raw pork or had contact with pigs [33]. The use of catheters for anesthesia and
imaging procedures has been associated with the introduction of α-hemolytic streptococci [24,34]. Anaerobic bacteria and other streptococci are otherwise uncommon causes of meningitis that are usually related to spread from brain abscess or parameningeal foci [35].

Pathogenesis

Bacterial seeding of the meninges can arise from hematogenous spread or spread from contiguous foci of infection. Direct invasion can be facilitated by anatomic defects secondary to trauma, such as when basilar skull fractures create a communication between the sinuses and the subarachnoid space [9,24]. Bacteremia can arise from simple colonization of the nasopharynx, though colonization alone is obviously not sufficient, since up to 40% of the population can be colonized with N. meningitidis and surveys in daycare centers show up to 60% S. pneumoniae carriage [36,37]. The bacterial species most commonly associated with meningitis bind receptors on microvascular endothelial cells, facilitating entry to the CNS [38]. Most meningitis pathogens also secrete immunoglobulin A proteases, facilitating immune evasion at mucosal sites [39]. Inadequate levels of antibody specific for the invading organism (such as occurs at the extremes of age or in acquired immunodeficiencies) and opsonophagocytic deficiencies (such as in asplenia, diabetes, or alcoholism) are the most commonly recognized risk factors for meningitis [36]. Individuals with terminal complement component deficiencies may experience recurrent episodes of meningococcal meningitis [16,37,40].

Once bacteria reach the CSF, both bacterial and host factors contribute to disease. Recognition of bacterial components leads to elaboration of inflammatory mediators such as tumor necrosis factor-α (TNF-α), interleukin-1, and interleukin-6; intrathecal TNF-α levels correlate with severity in the disruption of the blood-brain barrier [36]. Additional inflammation, triggers release of tissue factor (which aids thrombus formation and disrupts cerebral perfusion), nitric oxide (which disrupts autoregulation of blood flow and can have direct toxic effects on neurons), and matrix metalloproteinases (which can also disrupt endothelial junctions and impair neuronal function) [36,41]. Neuronal damage is further worsened by increases in intracranial pressure [41]. Antibiotics that rapidly lyse bacteria transiently increase in inflammation as a response to the release of bacterial cell wall components [36]. Adjunctive steroid therapy acts to decrease inflammation associated with bacterial lysis [36,42]. The body also deploys endogenous immunomodulators such as interleukin-10 and TNF-related apoptosis-inducing ligand (TRAIL), which has been shown to reduce neuronal damage in animal models [36,43].
The clinical consequence of these pathologic processes is a generalized disturbance of cerebral function. Early agitation, delirium, or mania may be noted. Lethargy progresses to obtundation and sometimes coma. Seizures and increased intracranial pressure can further depress levels of consciousness. Hyponatremia, which can be caused by the syndrome of inappropriate antidiuretic hormone (SIADH) secretion, cerebral salt wasting, or aggressive fluid resuscitation, may contribute to obtundation and seizures. Focal neurologic deficits may be observed; sensorineural deafness is particularly common [36,44].

Diagnosis

History

Patients with meningitis may be unable to give a coherent history. Patients found unresponsive should be evaluated with a high level of suspicion for meningitis. Patients with fever and derangement of cerebral function, even if there is another cause for the latter, must have meningitis excluded. Persons with coexistent alcoholism, general debility, head trauma, or neurosurgery are at higher risk for meningitis.

Classic meningeal symptoms are headache (often with photophobia), neck pain, fever, and mental status changes; in a case series, 95% of patients with bacterial meningitis had at least two of these four symptoms [45]. Symptoms of other foci of infection, such as pneumonia, otitis, or sinusitis, may also be present [46]. Any history of head trauma (including remote events) or recent clear nasal or ear discharges should be obtained. Recent antibiotics, which could interfere with culture results, should be noted. A history of exposure to a patient with known meningococcal disease is usually forthcoming if present. Travel history may aid the identification of regionally endemic pathogens.

Physical Examination

Nuchal rigidity suggests meningitis when present. Kernig’s and Brudzinski’s signs have low sensitivity but high specificity [46]. The initial neurologic examination should evaluate the mental status and the presence of focal deficits. Papilledema is rarely observed at presentation but alters the approach to LP when present. Serial examinations document any functional progression or improvement.

The systemic examination may give clues to the cause of meningitis. A thorough ear, nose, and throat examination can reveal possible foci leading to contiguous extension to the meninges. Petechiae or purpuric lesions strongly suggest meningococcal disease, though they may also be seen in other bacterial infections or in aseptic meningitis caused by
enteroviruses or rickettsiae. Needle aspiration or punch biopsy of skin lesions should be used to obtain material for Gram stain and culture. N. meningitidis can be detected on either culture or stain of skin specimens [9].

**Laboratory Tests**

Evaluation of the CSF is essential for the diagnosis of meningitis. The typical features of purulent CSF have been noted earlier. Neutrophil counts greater than 1,000 cells per μL are strongly associated with bacterial meningitis [9]. In rare cases, the CSF shows many organisms on Gram stain but few cells, implying rapidly progressive disease [9,45]. Elevated protein is also almost always present [9]. Severe depression of the CSF glucose (<20 mg per dL) is strong evidence for a pyogenic process, but CSF glucose is normal in over 50% of patients with bacterial meningitis [9]. Treatment with antibiotics prior to LP may alter CSF chemistries, resulting in higher glucose levels and lower protein levels, though cell counts are usually unaffected [47].

Cultures remain the mainstays of diagnosis. Blood cultures can be useful in identifying the causative agent of meningitis in cases where CSF cultures are unrevealing [48]. Ultimately, 60% to 90% of patients with community-acquired meningitis and purulent CSF have an organism isolated in culture [46]. CSF cryptococcal antigen assay should be considered; bacterial antigen detection tests offer little additional information [3,49]. Polymerase chain reaction (PCR) detection of bacterial DNA may provide more rapid and sensitive diagnosis, particularly in the setting of antibiotic pretreatment; however, these assays are not yet available in all settings [46,50].

Imaging studies are of secondary importance in the diagnosis of meningitis. Imaging of the chest and paranasal sinuses may identify other foci of infection. CT and magnetic resonance imaging (MRI) of the brain are most useful for evaluating complications of meningitis. Rapid deterioration should lead to consideration of subdural empyema, a collection between the dura and the arachnoid membrane [44,51]. A new focal neurologic abnormality, decreased level of consciousness, or cerebrovascular accident with a nonarterial distribution should prompt imaging for venous thrombophlebitis [44,51]. In postneurosurgical meningitis, imaging should evaluate for ventricular size, CSF leaks, and shunt malfunction [24].
Differential Diagnosis

Several pathogens other than pyogenic bacteria can cause clinical presentations and/or spinal fluid formulas that overlap with bacterial meningitis.

Viral meningitis can have initial clinical presentations similar to bacterial meningitis, with an early neutrophil predominance and a shift to lymphocytes over time [3]. Viral meningitis can be caused by a wide range of pathogens including enteroviruses, arboviruses such as West Nile virus (WNV) [52], herpes viruses such as herpes simplex virus (HSV) [53], and acute HIV infection [54].

Tuberculous meningitis most commonly presents with a mononuclear predominance in the CSF along with low glucose and high protein. However, some cases have a total leukocyte count in the range of purulent meningitis with a polymorphonuclear predominance [55]. A history of tuberculosis, risk factors for exposure, or the presence of an immunocompromising condition should raise suspicion, particularly in the setting of a subacute meningitis presentation [56]. If an initial diagnosis of bacterial meningitis is not confirmed by culture and the patient’s condition does not improve, repeat LP with studies for acid-fast bacilli should be performed. A switch to lymphocytic predominance, additional decrease in CSF glucose and increase in protein, positive chest radiograph, or well-founded clinical suspicion mandates institution of antituberculous therapy [55]. Acid-fast stains of CSF are positive in, at most, 60% of cases [56]. Nucleic acid amplification tests may facilitate earlier diagnosis, but there is a wide variability in their availability and sensitivity [57]. MRI is more likely than CT to visualize tuberculomas [58].

Parasitic infections can cause purulent meningitis. Primary amebic meningitis with Naegleria fowleri is acquired through freshwater exposure and presents similarly to acute bacterial meningitis. Diagnosis can be made on wet mount of CSF, though trophozoites are often mistaken for leukocytes; Centers for Disease Control and Prevention (CDC) can provide additional diagnostic modalities for suspected cases [59]. The nematode Strongyloides stercoralis is capable of establishing a cycle of autoinfection in immunosuppressed hosts, including those on oral corticosteroids. Migration of larvae from the gut can result in the deposition of enteric bacteria in the CNS, causing Gram-negative or polymicrobial meningitis [60].

Fungal meningitis may present with hypoglycorrhachia. An indolent course and lymphocytic CSF pleocytosis usually distinguish these from pyogenic infections, but Coccidioides immitis, an endemic fungus of the southwest United States, can have neutrophil predominance [61]. Cryptococcus neoformans is a major cause of meningitis in patients with
immunosuppressive conditions, though it can occur in normal hosts; *Cryptococcus gatti* is an emerging cause of cryptococcal meningitis in immunocompetent hosts [62]. Cryptococcal antigen assay of the CSF provides a sensitive means of diagnosis [63].

Parameningeal foci of infection, including epidural abscess, can present a purulent picture, usually with elevated protein and a normal glucose concentration [64]. Brain abscess that has ruptured into the ventricles may duplicate the clinical picture of bacterial meningitis. Localizing neurologic findings or isolation of an anaerobe or multiple organisms from the CSF should suggest one of these diagnoses [35].

Noninfectious conditions can cause meningeal signs and CSF findings that overlap with those of bacterial meningitis. Drug-induced meningitis may have a CSF formula indistinguishable from pyogenic infection; the most commonly implicated agents are nonsteroidal anti-inflammatories, antibiotics, immunomodulatory agents, and antiepileptics [65].

Postneurosurgical chemical meningitis, believed to be an inflammatory reaction to surgical manipulation, blood, or bone dust, can present with a CSF profile similar to bacterial meningitis. Although symptoms, CSF leukocytosis, and hypoglycorrhachia are usually less severe, no single parameter has been proven to distinguish between the two conditions. Given the risk of bacterial meningitis in the postneurosurgical population, antibiotics are often administered until CSF culture results are finalized [24,25,66].

## Therapy

Bacterial meningitis requires prompt initiation of antimicrobial and anti-inflammatory therapy, aggressive control of the potential complications, and prevention of disease spread [3]. Overall mortality from bacterial meningitis is in the range of 20% to 30% [45,67]. However, mortality rates are significantly influenced by both the pathogen, with *S. pneumoniae* among the most deadly, and the host, with elderly patients among the most susceptible [9,45]. Consequently, most patients should be treated in an intensive care setting.

## Antimicrobial Therapy

The principal consideration for choosing an antibiotic regimen for bacterial meningitis is that the agent(s) reach the CSF in concentrations that are bactericidal for the likely pathogens. Table 81.1 lists recommendations for therapy of bacterial meningitis in a variety of clinical settings. Initial therapy is usually selected empirically based on the age and underlying condition of the patient. Once the CSF Gram stain result is available, antimicrobial therapy can be targeted appropriately.

<sup>a</sup>Usual daily doses (schedules) for adults are as follows: ampicillin, 12 g/d (q4h); ceftriaxone, 4 g/d (q12h); ceftazidime, 6 g/d (q8h); naftillin, 12 g/d (q4h); penicillin G, 24 million U/d (q2–4h).

<sup>b</sup>Cefotaxime, 8–12 g/d, given q4–6h, is equally effective.

<sup>c</sup>Usual daily dose of vancomycin for adults is 2–3 g/d, given q8–12h, with body weight guiding dose and creatinine clearance guiding frequency of dosing. Troughs should be monitored with a goal of 15–20 mg/dL.
Cefepime, 6 g/d given q8h, may be used as an alternative.

Although CSF penetration of aminoglycosides is poor, some specialists recommend their use in these settings.

Consideration should be given to initial intrathecal administration in addition to intravenous administration.

In most areas, where methicillin resistance is common among isolates of S. aureus, vancomycin should be used and addition of nafcillin can be considered. In areas where methicillin resistance among S. aureus is still rare, nafcillin is the preferred agent.

The third-generation cephalosporins (ceftriaxone or cefotaxime) are the mainstays of therapy for community-acquired meningitis. These agents are active against most strains of S. pneumoniae and provide excellent coverage against N. meningitidis and Gram-negative bacilli (except Pseudomonas aeruginosa). S. pneumoniae with reduced susceptibility to the cephalosporins has been reported; this organism remains universally susceptible to vancomycin [68]. If the CSF Gram stain suggests pneumococci or is unrevealing, vancomycin should be given in addition to the cephalosporin until culture and sensitivity results are available [3]. Meropenem also demonstrates activity against many, but not all, cephalosporin-resistant strains of S. pneumoniae and has demonstrated clinical effectiveness for treatment of meningitis [68,69].

Ampicillin (or penicillin) should be included in the regimen for empiric therapy in neonates (<1 month old), individuals older than 50 years, patients with alcoholism, or those who are debilitated or immunosuppressed, for coverage of L. monocytogenes [19,70]. Initial therapy for postneurosurgical bacterial meningitis should include vancomycin plus either ceftazidime or cefepime to provide adequate coverage for methicillin-resistant staphylococci and P. aeruginosa. Resistance to antimicrobials, either at the outset or developing during treatment, can complicate therapy for Gram-negative organisms [71]. An increasing number of cases due to multidrug-resistant hospital-acquired organisms such as Acinetobacter sp. have been reported [72]. Few good treatment regimens exist for the cephalosporin-intolerant patient. Consequently, a trial of the third-generation cephalosporins (or meropenem) should be strongly considered unless there is a documented, serious intolerance. Vancomycin is the preferred alternative for treatment of pneumococcal meningitis. Moxifloxacin has activity against pneumococci, meningococci, and H. influenzae and has shown promise in animal models, but clinical experience is limited [3]. Trimethoprim–sulfamethoxazole is effective for the treatment of meningitis caused by L.
monocytogenes and many Gram-negative bacilli other than P. aeruginosa [73].

If S. pneumoniae is isolated, therapy should be adjusted based on the results of drug susceptibility testing. Fully susceptible organisms can be treated with third-generation cephalosporin alone. For resistant organisms, vancomycin and cephalosporin should be continued and the addition of rifampin considered [3]. Continued clinical instability after 48 hours of appropriate antibiotic therapy is an indication for repeat LP [3]. Repeat CSF samples should have a negative Gram stain and culture after at least 24 hours of effective antibiotic therapy [44].

The recommended duration of antimicrobial therapy for meningitis depends on the etiology and the clinical response. For infection with H. influenzae or meningococci, 7 to 10 days of therapy is adequate. S. pneumoniae is usually treated for 10 to 14 days, but longer durations may be needed for drug-resistant organisms. Gram-negative bacillary meningitis is typically treated for 3 weeks and staphylococcal disease, when accompanied by bacteremia, for 4 to 6 weeks [3].

**Anti-Inflammatory Therapy**

The role of endogenous mediators of inflammation in the pathogenesis of meningitis has provided a rationale for the use of anti-inflammatory agents. Dexamethasone, 0.15 mg per kg every 6 hours for 4 days, has been shown to reduce both mortality and neurologic sequelae [42,67]. However, the benefit appears to be primarily for pneumococcal meningitis [74,75]. Dexamethasone therapy should be initiated before or simultaneously with the first antimicrobial dose in patients with suspected or confirmed pneumococcal meningitis [3,67]. The recommended duration of steroid therapy is 4 days, but some studies in children suggest that 2 days may be adequate [42,76]. Current guidelines recommend discontinuing steroids when bacteria other than S. pneumoniae are isolated [3].

The benefits of steroid therapy seen in studies performed in industrialized countries have not been consistently observed in the developing world [77,78]; therefore, adjunctive dexamethasone is not routinely recommended in these settings.

**Supportive Therapy**

Treatment of meningitis also requires management of seizures and
increased intracranial pressure. Seizures should be controlled by anticonvulsants as necessary (see Chapter 151), and aspiration and hypoxia must be prevented. Severe cerebral edema with evidence of uncal or cerebellar herniation can be managed with CSF drainage, osmotherapy, and steroids [5]. Fluid management should be directed at maintenance of euvolemia [44].

Bacterial meningitis in the setting of CSF shunts presents additional considerations. The highest rates of cure (>80%) are obtained with initiation of antibiotics, removal of the entire shunt, temporary external drainage, and replacement of the shunt when follow-up CSF cultures are negative. One stage removal with immediate replacement of the device followed by antibiotics is associated with a 65% rate of cure. Antibiotics alone, usually only considered for less virulent organisms such as P. acnes and non-aureus staphylococci, are successful 35% of the time [3,24].

### Infection Control

Patients with *N. meningitidis* or *H. influenzae* type B meningitis should be managed with droplet precautions until 24 hours after initiation of antibiotics. Chemoprophylaxis is recommended for the situations described below. Dosing and duration are detailed in Table 81.2.

<sup>b</sup>In geographic areas where ciprofloxacin-resistant *N. meningitidis* has been reported, azithromycin 10 mg/kg for children or 500 mg for adults as a single dose can be used as an alternative.

For *N. meningitidis*, household and day care contacts as well as hospital personnel who have performed unprotected cardiopulmonary
resuscitation, intubation, or suctioning should receive chemoprophylaxis. Rifampin, ciprofloxacin, or ceftriaxone are the recommended agents [16]. A small number of ciprofloxacin-resistant *N. meningitidis* isolates have been reported in North Dakota and Minnesota [79]. Primary rifampin resistance is similarly rare but may develop secondarily in individuals who receive rifampin for prophylaxis [80]. Meningococcal vaccines (quadrivalent or serogroup B, depending on the setting) can be used as an adjunct to chemoprophylaxis to prevent late secondary cases in contacts or to control outbreaks of disease [16,17].

For *H. influenzae* type B disease, chemoprophylaxis is recommended for household contacts only if there is at least one child younger than 4 years who is not fully vaccinated or if there is an immunocompromised child in the household. In addition, if two or more cases have occurred in the same day-care group within 60 days, chemoprophylaxis is recommended. Rifampin is the recommended agent [21].
ENCEPHALITIS

Encephalitis is a more rare infection than meningitis and a far less uniform one. Although a specific diagnosis provides important prognostic and epidemiologic information, there are only a handful of treatable causes of encephalitis. Efforts should focus on identifying and addressing these causes. Infections of the brain that do not present as acute encephalitis but rather as subacute to chronic processes are not discussed further in this chapter.

Etiology

For almost half of all encephalitis cases in the United States, the etiology is not identified. Among the cases with a defined diagnosis, 50% are caused by viruses, with HSV and varicella zoster virus (VZV) being the most common [81–86]. Part of the diagnostic challenge stems from the sheer number and diversity of causative organisms. With improved diagnostic techniques, there is increased recognition of viruses such as Jamestown Canyon virus [87] and Powassan virus [88] as well as newly identified causative agents [89]. Many nonviral pathogens, including Mycobacterium tuberculosis, rickettsiae, Mycoplasma pneumoniae, Bartonella sp., Treponema pallidum, Borrelia burgdorferi, amoebae, L. monocytogenes, and Toxoplasma gondii, have all been associated with the syndrome [81–86]. In addition, immune-mediated encephalitis may have a similar presentation to infectious encephalitis. Autoimmune processes, such as anti-N-methyl-D-aspartate (NMDA) receptor and voltage gated potassium channel (VGKC) antibodies, are increasingly recognized causes of encephalitis, particularly in young women [84,90]. Table 81.3 lists the causes of infectious encephalitis that are indigenous to the United States in general prognostic categories. Despite the favorable prognosis, encephalitis caused by organisms listed in group 1 may be extremely severe, with prolonged unresponsiveness followed by gradual clearing.

Pathogenesis
Although HSV is the most common organism identified in encephalitis cases, the pathogenesis of herpes simplex encephalitis (HSE) is not entirely clear. The characteristic feature of HSE is its focal nature, an acute hemorrhagic necrotizing process with a predilection for the temporal lobe [91]. HSV persists in the trigeminal ganglia and is thought to travel up to the trigeminal or olfactory nerves at the time of
reactivation [91]. Studies of children with HSE have revealed defects in innate immunity [92,93].

Arboviruses are transmitted by the bite of their insect vector [94]. The insect vector inoculates the arboviruses, producing viremia. The organisms replicate in reticuloendothelial tissues, where a secondary viremia arises and infects the CNS. By the time encephalitic symptoms develop, the virus has usually been cleared from the circulation and specific antibody is present, facilitating diagnosis [94]. Blood transfusions and organ transplantation have also been a mechanism for transmission of WNV [52]. The mosquito-borne infections have seasonal prevalence in late summer and early fall. Prevalence in a given year can depend on weather trends affecting vectors. All arboviruses affect young children and the elderly more severely. Eastern equine encephalitis is the most virulent, causing death or severe neurologic sequelae in more than 60% of cases [95].

Rabies virus reaches the brain by spreading up neural pathways from its site of inoculation, a process that may take weeks to years. Saliva contains the virus, which is usually introduced by a bite or salivary contamination of an open wound [96]. In the past 30 years, the majority of cases in North America have been caused by bat rabies [97]. Human-to-human transmission has occurred through organ transplantation from donors with undiagnosed rabies [98]. Although it has never been documented, human-to-human transmission through saliva is theoretically possible; therefore, patients should be placed in strict isolation. Prophylaxis for rabies exposure consists of a combination of passive immunization with rabies immunoglobulin plus active immunization with rabies vaccine [99].

There are numerous noninfectious processes that can produce a clinical picture overlapping with infection-related encephalitis. Encephalitis associated with antineuronal antibodies fall into two main subtypes based on whether they bind intracellular targets or cell surface antigens [100,101]. The clinical presentation of the two forms overlap, frequently presenting with psychiatric symptoms, sleep disruption, movement disorders, and seizures. Antibodies associated with intracellular targets such as anti-Hu and anti-Ma2 are responsible for classic paraneoplastic syndromes and are strongly associated with underlying malignancy. The antibodies themselves are usually not pathogenic, but rather markers of a destructive cell-mediated response [101]. Antibodies to cell surface antigens, such as anti-NMDA and anti-VGKC, are directly pathogenic [101]. While they may occur in the setting of some malignancies (such as
ovarian teratoma), the association with cancer is weaker \[100,101\]. Postinfectious encephalitis can present with encephalopathy and demyelination days to weeks following a minor infection \[102\]. CNS vasculitis or sarcoidosis may manifest as acute or subacute encephalitis. Although the underlying etiologies are diverse, they share the common feature of vessel wall inflammation leading to ischemia and infarction \[103\].

**Diagnosis**

The diagnostic process is directed principally at identifying treatable causes of encephalitis, especially HSE or nonviral pathogens \[84,86,104\].

**History**

The epidemiologic features reviewed earlier (see Pathogenesis) are major contributors to diagnosis. A history of foreign travel may widen the differential diagnosis beyond the considerations reviewed here. Establishing the host’s immune status, and potential for occult HIV infection, will also help guide the diagnostic workup \[104,105\]. A history of recent infection or a prominent component of psychiatric disturbance or movement disorder raises the likelihood of immune-mediated processes \[100,102\].

Fever and headache are common. A neurologic presentation may occur, with seizures, mania, personality change, or another neuropsychiatric disorder as the principal signs \[104,105\]. Focal neurologic findings, including aphasia, suggest a diagnosis of HSE \[106\]. Aversion to water, refusal to swallow, and delirious behavior are classic features of “furious” rabies but are absent in 20% to 40% of cases presenting with flaccid paralysis \[96,107\]. Flaccid paralysis mimicking poliomyelitis has also been observed in WNV encephalitis and with certain enteroviruses \[52,108\].

**Physical Examination**

The critical component of the physical examination is to determine whether an anatomic focus of abnormality is present, increasing the likelihood of HSE. Typical skin findings may suggest diagnoses such as Rocky Mountain spotted fever, measles, or herpes zoster.
Laboratory Tests

Analysis of CSF is the most important diagnostic procedure; 20 mL should be obtained if possible with 5 to 10 mL frozen for possible future studies [104]. Opening pressure should be measured [104]. The CSF in encephalitis usually fits the aseptic picture described earlier. It may be normal early in the course of infection or in immunocompromised patients [104]. The presence of red blood cells suggests a hemorrhagic type of encephalitis, such as HSE, but is not diagnostic [91]. Eosinophils suggest infection with helminths, treponemes, rickettsiae, coccidiomycosis, toxoplasmosis, or *M. pneumoniae* [86].

Given its prevalence and the availability of specific therapy, PCR for HSV should be performed on CSF in all cases [86]. False-negative results can occur early in the disease. A repeat HSV PCR in 3 to 7 days is recommended if the clinical scenario remains consistent with HSV and no alternative diagnosis has emerged; testing for HSV intrathecal antibody production can be considered in cases with negative PCR despite high clinical suspicion [104,109].

Enteroviral PCR and VZV PCR should be sent from CSF for most adult cases, given their frequency as causative agents of encephalitis. VZV CSF IgG and IgM may also be necessary as the sensitivity of PCR may be low [104]. Treponemal testing (VDRL) and cryptococcal antigen testing of CSF should also be considered in initial evaluation [104]. When evidence of involvement outside the CNS is present, evaluation of other tissues may be helpful. Respiratory viral testing or cultures should be pursued in patient with respiratory symptoms, culture and enteroviral testing of stool in patients with diarrhea, and skin biopsy in patients with lesions [104]. PCR of serum can aid the diagnosis of ehrlichiosis, whereas PCR of lymph node tissue can detect *B. henselae* [86].

Diagnosis of most other causes of encephalitis relies on serologic testing. In arboviral infection, antibody is usually present at the onset of neurologic signs and is sufficiently rare in the general population to permit presumptive diagnosis [86]. The presence of antibody to *T. pallidum*, *B. burgdorferi*, rickettsia, or ehrlichia may reflect prior infection but is sufficient evidence to warrant treatment [86,105]. Detection of pathogen-specific antibody in the CSF can provide more convincing evidence of the etiology of encephalitis, with a serum to CSF antibody ratio of less than 20 suggesting intrathecal production of antibody. For most causes of encephalitis listed in Table 81.3, the demonstration of a significant increase in antibody titer is required for diagnosis. The preferred approach is the comparison of a stored sample from the acute phase of infection to a sample obtained 2 to 4 weeks later [86].

For rabies, the reference standard is detection of viral nucleocapsid by
fluorescent antibody staining of brain tissue, but this is often only obtained postmortem. Premortem diagnostic techniques exploit the fact that rabies virus nucleocapsids are concentrated in the nerve endings surrounding the base of hair follicles; nuchal skin biopsy followed by fluorescent staining or RT-PCR for virus has the highest sensitivity [110].

Diagnosis of amebic encephalitis due to *N. fowleri*, *Balamuthia mandrillaris*, and *Acanthamoeba* spp. remains challenging. *N. fowleri* can be observed on CSF wet mount [104]. *B. mandrillaris* may be accompanied by nodular skin lesions with evidence of the organism on biopsy [111]. The CDC can support diagnostic testing which can include immunohistochemistry and PCR testing [59,104].

Although they share no distinct profile, patients with encephalitis due to noninfectious causes generally have lower CSF white blood cell counts and protein levels [82]. Recurrent encephalitis, patients with cerebellar dysfunction, and presentations with psychotic features are somewhat more likely to be secondary to noninfectious etiologies [82]. Oligoclonal bands and abnormal IgG index are often present in the CSF in immunemediated encephalitis, prompting the recommendation to include these tests in initial encephalitis evaluations in recent guidelines [104]. CSF assay for known antineuronal antibodies should be performed [100,101].

Neuroimaging, preferably MRI, is recommended for the evaluation of all patients with suspected encephalitis [86,104]. The findings in viral encephalitis are most often nonspecific, but the identification of mass lesions or infarcts will redirect the diagnostic workup toward brain abscess, vasculitis, or endocarditis. The finding of focal encephalitis, particularly involving the temporal lobes, is suggestive of HSE [86,104], though VZV encephalitis can have similar neuroimaging features [112]. Characteristic abnormalities may not be seen initially; if the clinical suspicion is high, imaging studies should also be repeated after several days.

Electroencephalography (EEG) may provide early clues to a diagnosis before imaging changes are apparent, but the abnormalities usually are less specific. In patients with HSE, 80% have a temporal focus, although serial studies are often required to detect these changes [104,105]. EEG may also identify epileptiform discharges as a cause of obtundation in patients without overt seizure activity [104]. Normal EEG is associated with better prognosis [113].

With the advent of new molecular approaches and improved serologic diagnostics, brain biopsy is less commonly performed. However, it should be considered in selected situations, such as when a patient continues to deteriorate on acyclovir [109]. In the largest brain biopsy series reported, 9% of all patients with suspected HSE had another treatable disorder [114]. Neuroimaging should be used to guide sampling of abnormal tissue. Yield is likely to be higher earlier in disease. Specimens should be
sent directly for culture, PCR, and immunofluorescence as well as fixed for routine histology with staining for pathogen detection [86].

**Therapy**

Empiric therapy with acyclovir (10 mg per kg every 8 hours in adults) should be initiated in all patients with encephalitis pending results of the diagnostic workup for HSE [86]. Subsequent management depends on the clinical response and HSV PCR results. Total duration of therapy in confirmed HSE is at least 14 to 21 days [86]. Repeat HSV PCR is recommended prior to stopping therapy in HSE patients who continue to exhibit encephalitic features, with continuation of acyclovir if the repeat PCR is positive [86]. HSV resistance to acyclovir in immunocompetent adults is extremely rare [115]. There is no benefit to continuing extended oral therapy with valacyclovir after completion of intravenous acyclovir therapy [116].

Empiric doxycycline therapy (100 mg twice a day) should be considered for patients presenting with clinical suspicion of rickettsial or ehrlichial diseases in the summer months [86]. Early institution of tetracyclines reduces mortality in Rocky Mountain spotted fever. Therapy should be given in confirmed cases until the patient has been afebrile for 2 to 3 days [117].

Specific therapy is available for most nonviral microbial causes of encephalitis. Neurosyphilis should be treated with 10 to 14 days of high-dose penicillin G [118]. Meningoencephalitis caused by the Lyme disease spirochete is treated with ceftriaxone (2 g IV once daily) for 14 days [119]. Treatment for toxoplasmic encephalitis consists of pyrimethamine plus either sulfadiazine or clindamycin [120]. Neurologic disease in the setting of *Bartonella* sp. is treated with doxycycline and rifampin in adults [121].

Antiviral therapy may be efficacious for some non-HSE forms of viral encephalitis. Although efficacy has not been established in large clinical trials, acyclovir therapy is recommended for VZV encephalitis based on limited evidence of improved outcomes in small case series [86]. Ribavirin can be considered for cases of encephalitis secondary to rabies or measles viruses, but there is little published experience. In influenza-related encephalitis with a susceptible strain, oseltamivir is recommended [86].

For immune-mediated encephalitis, treatment of paraneoplastic syndromes relies upon treatment of the underlying malignancy triggering the cross-reactive response in combination with immune modulating
therapies [101]. For syndromes caused by antibodies binding cell surface antigens, antibody removal and/or suppression of the immune response can yield clinical improvement. Current treatments rely on high dose steroids, intravenous immunoglobulin, and/or plasma exchange, with rituximab and cyclophosphamide deployed as second-line treatment [101].

Treatment for most cases of encephalitis is supportive, with particular attention to the management of cerebral edema and seizures [122]. Status epilepticus (see Chapter 151) may produce additional neurologic damage. Intubation may frequently be necessary to prevent aspiration and to provide ventilatory assistance. The risks of nosocomial infection, particularly pneumonia, are very high for patients with prolonged periods of unconsciousness.
BRAIN ABSCESS

Etiology and Pathogenesis

Brain abscesses most commonly arise in the setting of a predisposing factor such as immunosuppression, contiguous focus of infection, disruption of the natural protective barriers of the brain, or bacteremia. The abscess etiology is strongly influenced by these predisposing factors. In the setting of immunosuppression, brain abscesses are more likely to be caused by atypical bacteria such as *M. tuberculosis* and Nocardia or nonbacterial causes such as fungi (*Aspergillus*, sp.) or parasites (*Toxoplasma gondii*, *Acanthamoeba* sp.). Infections following neurosurgical procedures or head trauma are commonly caused by skin flora or gram-negative bacilli. Abscesses caused by spread from contiguous foci are often streptococci, though *S. aureus* and polymicrobial infections including anaerobes are also seen. Hematogenously seeded abscesses are commonly staphylococcal and streptococcal species, though anaerobes (such as *Fusobacterium necrophorum* in Lemierre’s syndrome), Nocardia, and other pathogens can also hematogenously seed the CNS [35]. Sequencing of 16S ribosomal RNA from brain abscess aspirates has revealed a more diverse array of organisms than had previously been isolated in culture [123].

For the development of brain abscesses, initial infection of brain tissue leads to a focus of inflammation known as early cerebritis. This area appears hypodense on CT scan and will enhance with contrast administration. The area of cerebritis expands and develops a central area of necrosis in the late cerebritis stage. A ring-enhancing wall of well-vascularized tissue then separates the necrotic, infected area from healthy surrounding tissue as the abscess matures into the capsule stage [35,51].

Diagnosis

Brain abscess usually presents more as a focal mass lesion—with headache, seizures, or neurological deficit—than as an infectious disease; fever is often not present [35]. Cranial CT or MRI aids localization of abscesses, staging the disease, and evaluation of the underlying cause [51]. Blood cultures and CSF cultures are positive in 25% of brain abscesses, but LP is contraindicated for most cases due to potential mass effects. Drainage of contiguous foci with material sent for culture is crucial for both treatment and diagnosis. If the causative agent has not been identified from other sources, aspiration of the brain abscess itself is indicated. Aspirate should be sent for gram stain, aerobic, and anaerobic
cultures in all cases. If risk factors for tuberculosis are present, mycobacterial stain and culture should be performed. If the patient is immunosuppressed, cultures for Nocardia and fungus should be performed along with PCR for *T. gondii* [35].

**Therapy**

Initial antimicrobial therapy should be based on the pathogens predicted by the probable underlying source. Unless a diagnostic aspiration is imminent and the patient is stable, empiric therapy should not be delayed pending culture as rapid decompensation can occur. Standard empiric therapy consists of ceftriaxone plus metronidazole to provide coverage for aerobic Gram-positive cocci, anaerobes, and aerobic Gram-negative bacilli. Antistaphylococcal therapy may also be required if *S. aureus* is in the differential diagnosis. Postneurosurgical abscesses should be treated with vancomycin, cefepime, and metronidazole as initial therapy. Patients with HIV should have therapy for toxoplasmosis added if they have a history of a positive serology and empiric therapy for Nocardia and fungi should be considered in initial management of transplant patients. Duration of therapy is not well defined. Most bacterial brain abscesses require a prolonged 6- to 8-week course of intravenous antibiotics with serial cranial imaging to assess response to therapy [35,124].

Prolonged antimicrobial therapy alone is curative for some patients, especially when the lesions are small (<2.5 cm) and do not have a well-defined capsule by CT criteria. However, in the absence of a contraindication, prompt aspiration of the abscess contents using CT-guided stereotactic techniques is usually recommended. This provides confirmation of the diagnosis, material for culture, and possible adequate drainage of the focus of infection. In patients with multiple abscesses, the largest lesions are usually aspirated [35].
PARAMENINGEAL FOCI

Subdural Empyema

Subdural empyema usually arises from the same foci as brain abscess or as a complication of meningitis [44,125]. The infection spreads through venous drainage into intracranial vessels, which course through the subdural space. The clinical features of subdural empyema are caused by local inflammation and cerebral edema, leading to increased intracranial pressure and herniation. Patients demonstrate depression of consciousness, hemiplegia, focal seizures, papilledema, and meningitic signs [125]. MRI is the most sensitive diagnostic modality [51]. Surgical decompression and drainage are urgent adjuncts to antibiotic therapy [125].

Dural Sinus Thrombophlebitis

Major dural sinus thrombophlebitis may occur in pyogenic meningitis but more often arises from contiguous spread of sinusitis, mastoiditis, otitis, or cranial skin and soft tissue infection. The microbiology reflects that of acute infection at these sites: S. aureus, S. pneumoniae or other streptococci, and anaerobes. Clinical signs and symptoms vary with the thrombus location. For instance, sagittal sinus thrombophlebitis may cause seizures and hemiplegia, whereas cavernous sinus thrombophlebitis presents with proptosis, marked chemosis, and ophthalmoplegia. Sigmoid sinus thrombophlebitis may give no neurologic signs but produce persistent fever in a case of chronic otitis media and mastoiditis. CT and MRI often can demonstrate thrombosis in the dural sinuses. Antibiotics and drainage or excision of the focus from which the problem originates are the mainstays of therapy. The merits of anticoagulation are controversial due to the propensity of venous infarcts to become hemorrhagic [126].

Spinal Epidural Abscess

Spinal epidural abscess is an infection that may be seeded during bacteremia or occur as a complication of vertebral osteomyelitis or surgery. More than half of cases are caused by S. aureus [64,127]. The classic triad of symptoms is back pain, fever, and neurologic
deficit, though many patients do not demonstrate all three [127]. Percussion tenderness is not always present [127]. Most patients have elevated C-reactive protein or erythrocyte sedimentation rate and approximately 60% have positive blood cultures [127]. Early recognition of epidural abscess is critical because neurologic progression may be rapid and irreversible. MRI should be performed quickly to distinguish the extent of spinal involvement and to evaluate adjacent structures [64].

Immediate neurosurgical consultation is mandatory. The goals of prompt surgical intervention are to prevent or relieve paraplegia and to obtain material for microbiological diagnosis. A nonoperative approach has been used with increasing frequency, particularly in patients with poor medical condition or if the neurologic condition is stable and a microbial etiology is identified quickly from cultures of blood or aspirated material [128]. However, the neurological condition may deteriorate rapidly even after several weeks of antimicrobial therapy. MRI scanning and neurosurgical consultation should be available on an urgent basis for patients who are managed nonoperatively.

Blood cultures and image-guided abscess aspirate cultures should be obtained prior to initiation of antibiotic therapy in neurologically stable patients unless signs of impending sepsis are present [64]. Antistaphylococcal antibiotics should be started after cultures are obtained; Gram-negative coverage should be considered in intravenous drug abusers or patients with a documented Gram-negative focus elsewhere, such as the urinary tract. Therapy is adjusted based on the results of Gram stains and cultures. There are no controlled studies to support a specific duration of antibiotic therapy. Six weeks of therapy with close clinical monitoring and serial measurement of inflammatory markers is recommended. Repeat imaging should be obtained only if clinical improvement is not observed [64].

Advances in CNS infections, based on randomized controlled trials or meta-analyses, are summarized in Table 81.4.

meningitis [76].

- Dexamethasone treatment begun just prior to the institution of antibiotic therapy reduces mortality and the incidence of neurologic sequelae in adults with acute bacterial meningitis [67].

- Silver impregnated external ventricular catheters reduce the incidence of central nervous system infection compared with plain catheters [31].

- Acyclovir treatment reduces the mortality and the incidence of neurologic sequelae in herpes simplex virus encephalitis [130].

- Following completion of a standard course of intravenous acyclovir for herpes simplex encephalitis, an extended course of oral valacyclovir did not improve neurologic outcomes [116].

Tuberculosis (TB) continues to cause significant morbidity and mortality worldwide. In 2013, there were an estimated 9.0 million new cases and 1.5 million deaths due to tuberculosis [1]. Globally, the total number of tuberculosis cases is declining, with an estimated 37 million lives saved since 2000 due to intensified diagnosis and treatment. Between 1990 and 2013, the TB prevalence rate fell by 41% globally. In the United States, incident tuberculosis cases have been declining since 1992 and reached a historic low in 2014 at 9,412 [2]. However, the rate of decline in incidence is the lowest in a decade. Foreign-born individuals continue to shoulder a disproportionate burden of TB, with a rate 13.4 times higher than U.S.-born persons. Racial and ethnic disparities persist, signaling a need to increase access to TB care services for our vulnerable populations.

A threat to TB control efforts worldwide has been the rise of multidrug-resistant (MDR) and extensively drug-resistant (XDR) forms of tuberculosis. Since the outbreak of XDR tuberculosis in rural South Africa associated with a high and rapid mortality, MDR and XDR TB epidemics are increasingly recognized globally [1,3]. In 2013, there were an estimated 480,000 cases of MDR-TB globally, 9% of which were estimated to be XDR. Even more worrisome is the gap between identification of cases and treatment: only 45% of cases who could have been detected were identified, with only 20% estimated to have initiated treatment [1]. If all TB patients were able to be tested for MDR-TB, more than half of the detected MDR-TB cases would have been identified from India, China, and the Russian Federation. While the accuracy of these estimates is limited by the availability of diagnostic testing, they have implications for choosing empiric TB regimens for individuals who hail from areas with larger burdens of drug-resistant TB.

The proportion of newly diagnosed tuberculosis patients who require
hospitalization each year is poorly characterized. One large urban hospital reported that tuberculosis accounted for 1% of medical intensive care unit (ICU) admissions over a 15-year period [4]. Epidemiologic studies show that between 3% and 24% of hospitalized tuberculosis patients require treatment in an ICU and that between 2% and 13% require mechanical ventilation [4,5]. Although overall mortality from tuberculosis in the United States has been around 5% for the past decade [6], mortality remains particularly high (50% to 60%) among patients with tuberculosis-associated respiratory failure requiring mechanical ventilation [5,7,8]. Factors associated with mortality include multiorgan failure, malnutrition, renal failure, immunosuppression, and delayed diagnosis [5,7–10].
PATHOGENESIS

The pathogenesis of tuberculosis is a two-stage process, which can be divided into tuberculosis infection and progression to disease \([11,12]\). These stages are reflective of the risk factors that should be considered when determining the likelihood a patient has tuberculosis (Table 82.1). Tuberculosis infection, with rare exceptions, results from the airborne transmission of tubercle bacilli. Upon reaching the alveoli of a susceptible host, the tubercle bacilli multiply to produce a localized pneumonia, spread to involve the hilar lymph nodes, then enter the bloodstream through the thoracic duct, and disseminate throughout the body. This primary infection is usually clinically unapparent. Most patients develop cell-mediated immunity to \(M.\) \(\text{tuberculosis}\), which brings the infection under control over a period of weeks. Despite initial immunologic control of tuberculosis infection, viable tubercle bacilli remain in scattered foci as latent tuberculosis infection that is left untreated may persist for life \([13]\).

**Risks for progression to active tuberculosis (tuberculin/IGRA status positive or unknown)**

1. Known or suspected HIV infection
2. Other immunosuppressive conditions
   - Tumor necrosis factor-α inhibitors, high-dose corticosteroids, and other immunosuppressive therapy
3. Recent tuberculosis infection
4. Presence of upper-lobe scars compatible with inactive tuberculosis
5. Certain medical conditions
   - Diabetes mellitus
   - Silicosis
   - Chronic renal failure
   - Gastrectomy or other conditions associated with weight loss

The second stage is the development of active tuberculosis, which occurs at a variable rate dependent upon the person’s age at infection and other medical conditions [12]. Progression from latent to active tuberculosis, termed *reactivation*, is much more frequent in people with certain conditions, particularly HIV infection ([Table 82.1]) [12,14]. Patients with advanced HIV have a 10 times greater risk, whereas those on effective antiretroviral therapy (ART) still have twice the risk of an uninfected person [12]. In most cases, reactivation of tuberculosis causes pulmonary disease, but reactivation can occur at any site where a latent focus was established during the initial infection [11]. Disseminated disease may also occur and is believed to result from the erosion of a tuberculous focus directly into a blood vessel [15]. In a critically ill patient, the presence of any risk factor for infection or progression should prompt consideration of tuberculosis in the differential diagnosis.
Physicians in intensive care settings face the challenge of maintaining an appropriate index of suspicion for tuberculosis when it is a relatively rare cause of critical illness. Prompt recognition of tuberculosis and early institution of effective multiple-drug therapy are required to achieve the dual goals of successfully treating patients and preventing nosocomial tuberculosis transmission. Delays in diagnosis are unfortunately common and have been noted in more than half of patients admitted to community hospitals [16]. Concomitant nontuberculous infections occur in up to a third of patients and can lead to delays in diagnosis [8]. Fluoroquinolones are a well-established therapy for M. tuberculosis [17] and should be avoided in patients in whom tuberculosis is suspected. Use of fluoroquinolones can be associated with clinical improvement, delaying the diagnosis of tuberculosis, which is associated with worsened outcomes, including excess mortality [18,19–25]. Linezolid also has activity against M. tuberculosis and is one of the agents utilized to treat drug-resistant tuberculosis [26,27]. Linezolid is used to treat resistant gram-positive bacteria including methicillin-resistant Staphylococcus aureus (MRSA). MRSA pneumonia can present with cavitary pneumonia similar to TB, and so linezolid should be avoided in patients in whom tuberculosis is suspected.

Tuberculosis may present as the primary cause of a life-threatening illness, but it may also be a coincidental illness in patients being treated for another condition [8] (Fig. 82.1). The symptoms and signs of tuberculosis are variable and depend upon the site and extent of the disease [5,7,8]. The history of a chronic, progressive illness with fever, night sweats, and weight loss, with or without a chronic cough, is most suggestive of tuberculosis. However, obtaining an accurate history can be difficult and tuberculosis patients often report the acute onset of symptoms [7,28,29]. Cough duration is a poor predictor of tuberculosis, particularly in the context of underlying HIV disease, and should not be used to differentiate a respiratory syndrome due to pulmonary tuberculosis from other etiologies [30]. A variety of laboratory abnormalities have been associated with tuberculosis, including anemia, hypoalbuminemia, elevated alkaline phosphatase, and hyponatremia, but are nonspecific [11,31].
FIGURE 82.1 Chest radiograph of a 41-year-old homeless patient who was hospitalized with multiple fractures, including the right clavicle, after being hit by a car. The patient denied all respiratory symptoms despite having extensive bilateral upper-lobe fibronodular and cavitary disease. Sputum samples were smear positive and grew M. tuberculosis.

Pulmonary Tuberculosis

Pulmonary tuberculosis is the most common form of the disease, accounting for 79% of cases in the United States in 2013, with 9% of those with both pulmonary and extrapulmonary disease [6]. Extrapulmonary tuberculosis is more common among patients who are female, born outside the United States, and who have HIV disease [32]. Acute respiratory failure, which occurs in 2% to 13% of hospitalized tuberculosis cases, is the most common reason for admission to an ICU [4,5,10,29]. Although chronic cough and fevers are usually present, other symptoms suggestive of pulmonary tuberculosis include weight loss, dyspnea, and hemoptysis [11]. Of note, dyspnea may be minimal despite fairly extensive lung destruction. Hemoptysis occurs in about 20% of patients and occasionally can be massive [33]. Pulmonary tuberculosis may also be asymptomatic, occurring in patients with primarily extrapulmonary disease, or may be a coincidental finding (Fig. 82.1).

Definitively diagnosing pulmonary tuberculosis relies upon the collection of respiratory samples for smear and culture. More recently, there has been an increasing role for the use of nucleic acid amplification tests for diagnosing pulmonary tuberculosis at the point of care [34]. Sputum samples should be considered for symptomatic patients at risk
for tuberculosis even when the chest radiograph appears normal. Positive sputum cultures for M. tuberculosis in the absence of radiographic abnormalities appear more commonly among individuals with underlying HIV disease [35–37]. The proportion of hospitalized tuberculosis patients who have a positive sputum smear ranges between 35% and 65% [7,9]. A minimum of three sputa or other lower respiratory tract specimens should be collected when pulmonary, pleural, or disseminated tuberculosis is suspected. The samples should be collected 8 hours apart, preferably with at least one early morning specimen [38].

Patients who are unable to spontaneously produce sputum should have samples induced using nebulized hypertonic saline [11]. Bronchoscopic specimens are not more sensitive and should not be considered a replacement for three expectorated or induced sputa [39]. Bronchoscopy is generally helpful if alternative diagnoses are being sought or if a tissue biopsy is needed. For selected patients, including young children, who either can’t tolerate the nebulizer or still don’t produce an adequate sputum sample, gastric aspirates should be obtained. When acid-fast bacilli (AFB) smears of respiratory secretions are negative, other specimens that may yield a diagnosis include pleural fluid, pleural biopsy, or transbronchial biopsy [11,40]. More invasive procedures such as transthoracic needle biopsy of the lung or mediastinal lymph nodes or open lung biopsy may be necessary under certain circumstances.

Pleural Tuberculosis

Pleural tuberculosis presents in two forms, commonly as tuberculous pleuritis and rarely as tuberculous empyema [11,41]. Tuberculous pleuritis occurs in 6% of HIV-negative and 11% of HIV-positive patients [42], and the incidence increases with declining CD4 cell counts [43]. It results from the rupture of a granuloma into the pleural space and may occur alone or in conjunction with pulmonary disease [41]. Often patients are asymptomatic but some present with acute symptoms of fever and chest pain, suggesting a viral or bacterial cause. The pathogenesis is primarily an immunologic reaction with very few tubercle bacilli actually present in the pleural space. Radiographically, a unilateral effusion covering less than half the hemithorax is typical. Untreated, tuberculous pleuritis often resolves but these patients are at high risk for recurrent pulmonary disease. Tuberculous empyema is much less common and results from the entry of large numbers of bacilli into the pleural space due the rupture of an adjacent cavity or development of a bronchopleural fistula [44].
Pleural fluid and tissue biopsy are typically needed to definitively diagnose tuberculous pleuritis. Sputum specimens should also be collected to evaluate for concurrent pulmonary disease. The pleural fluid most often shows a serous exudate with elevated protein and lactate dehydrogenase levels, low to normal glucose levels, and a pH range between 7.05 and 7.45 [42,45]. Early in the process, the fluid has a predominance of polymorphonuclear leukocytes that are replaced by lymphocytes within days. Adenosine deaminase (ADA) and other biochemical markers have been studied extensively, alone and in combination, as markers for diagnosing tuberculous pleuritis. Studies have supported measuring ADA levels, especially isoenzyme 2, showing additive diagnostic sensitivity and specificity when combined with other tests [46]. ADA levels may be useful in settings that lack the capacity to do cultures, but should not replace a pleural biopsy, which provides tissue for culture and pathology review.

AFB smears of pleural fluid and pleural biopsies are rarely positive (10% to 20%). The earliest presumptive diagnosis is provided by pathologic findings of granulomas with or without caseation, which are seen histologically in 60% of specimens [41]. Pleural fluid cultures are positive in only 20% to 30%. The yield increases slightly with multiple samples but waiting for positive cultures will delay the initiation of tuberculosis treatment [47]. Pleural biopsies are culture positive in 55% to 85% of specimens and should be sought whenever tuberculosis is considered a likely diagnosis.

Disseminated Tuberculosis

Disseminated tuberculosis refers to multiorgan involvement and may occur during progressive primary infection or as a complication of chronic tuberculosis [40,48]. The term *miliary tuberculosis*, which refers to the histologic appearance of diffuse nodular lesions resembling millet seeds, has historically been used interchangeably with disseminated disease. Now the term miliary is generally reserved to describe a diffuse micronodular infiltrate on the chest radiograph (Fig. 82.2). Young children and immunocompromised patients are at greatest risk for disseminated tuberculosis. However, a chronic, cryptic form of disease, termed *late generalized tuberculosis*, can occur in the elderly or those with other underlying illnesses [15]. In this cryptic form of disseminated tuberculosis, miliary infiltrates are rare and a diagnosis is often made postmortem.
Clinical evidence of dissemination is common among HIV-positive individuals living in hyperendemic tuberculosis settings [49–51] and thus vigilance for this presentation is critical when managing patients who are from these areas. Dissemination is also seen in up to 33% of solid-organ transplantation associated tuberculosis cases [52,53]. The presentations range from generalized lymphadenopathy to sepsis [49,50] and fulminant respiratory failure [54]. The duration of symptoms before diagnosis may vary from 1 week to over a year. Fever and other constitutional symptoms are seen in over 90%, respiratory symptoms in 75%, abdominal symptoms in 25%, and central nervous system symptoms in 20%. In some reports, the presentation of disseminated tuberculosis has been similar to that of gram-negative sepsis [55]. Acute respiratory failure is uncommon but a well-characterized complication of disseminated or miliary tuberculosis [29,56]. Laboratory abnormalities in disseminated disease are nonspecific. Anemia is common, but leukocyte and platelet counts range from markedly elevated to severely depressed [48]. Alkaline phosphatase levels are frequently elevated, likely related to granulomatous hepatitis. Chest radiographic findings are variable and may demonstrate miliary nodules of 1 to 3 mm in diameter or larger nodules of 5 to 7 mm. In about 10% of disseminated cases, radiographs will be normal, particularly early in the illness. Virtually any body fluid, tissue, or organ may yield a diagnosis, particularly with clinical or laboratory abnormalities that suggest an extrapulmonary site of disease. Because extrapulmonary tuberculosis usually involves a lower burden of organisms compared with pulmonary disease, histological examination and culture of biopsy specimens often provides the greatest diagnostic yield. Sputum smears should be examined for AFB, but are positive in less than a third of patients with miliary tuberculosis. Histology and cultures of transbronchial,
thoracoscopic, or traditional open lung biopsy will usually confirm the diagnosis. However, a careful search for chronic skin lesions, scrotal involvement, or lymphadenopathy may disclose other more accessible sites for a diagnostic biopsy [57]. Urine and stool cultures are easily obtainable and also may provide the diagnosis. Lumbar puncture should be considered for patients with headache or other central nervous system symptoms because meningitis is found in nearly 20% of patients with disseminated tuberculosis. Mycobacterial blood cultures are positive for 26% to 42% of HIV-positive individuals and is the only culture-positive specimen in some [49,50,58]. Other potentially useful diagnostic tests include culture of gastric aspirates and biopsy specimens of liver or bone marrow. Among those with disseminated tuberculosis, granulomas are seen in about 90% of liver biopsies; the yield is lower from bone marrow biopsy unless pancytopenia is present [59].

Central Nervous System Tuberculosis

Tuberculosis involving the central nervous system may present as meningitis, as one or more parenchymal tuberculomas, or as a combination of both [60,61]. The clinical presentation varies from an indolent illness with headache and subtle changes in mental status to more acute presentations. Focal neurologic symptoms and signs may result from a tuberculoma causing a localized mass effect or from basilar meningitis affecting the cranial nerves directly or causing infarction of intracranial arteries [60]. Evidence of active or inactive tuberculosis at another site is noted in about three-fourths of cases, most often miliary infiltrates on chest radiographs. Tuberculomas of the central nervous system are readily detected by computed tomography (Fig. 82.3), but magnetic resonance imaging is often needed to detect basilar meningitis [61]. Tuberculous meningitis and tuberculomas are more common among HIV-positive individuals and present with signs, symptoms, and laboratory findings that are similar to those found in individuals who are HIV-negative [62].
Computed tomographic scan of a 45-year-old patient with AIDS, known to be TST (+) but never completed latent treatment, who presented with a headache, expressive aphasia, and neologisms. The scan shows a tuberculoma with marked surrounding edema. Cerebral spinal fluid showed a white blood cell count of 675 (100% lymphocytes), glucose 42 mg/dL, and protein 246 mg/dL. CSF cultures were negative, but the diagnosis of isoniazid-resistant tuberculosis was confirmed by excisional biopsy.

Rapid diagnosis and treatment is critical to patient survival and favorable neurologic outcomes after tuberculous meningitis. A definitive diagnosis can be difficult though, and antituberculous treatment should be initiated immediately in individuals suspected of neurologic disease because delays in therapy are correlated with outcomes. Evaluation of cerebral spinal fluid (CSF), although often nonspecific, is important for diagnosing central nervous system (CNS) tuberculosis. The CSF findings classically described are a lymphocytic pleocytosis, low glucose, and an elevated protein. However, the absence of these findings does not exclude the diagnosis because the white cell count may range widely, a polymorphonuclear predominance occurs in up to 30%, and the protein and glucose may be normal [60,61]. AFB smears of CSF are positive in only 10% to 20% of cases, and cultures are positive in <50%. Because disseminated disease is common with tuberculous meningitis, AFB cultures sent from other sources, including sputum, urine, and stool, may provide a diagnostic smear or culture. CNS tuberculomas may be
diagnosed by a typical radiographic appearance and response to treatment, but definitive diagnosis usually requires biopsy or surgical excision.

**Other Forms of Extrapulmonary Tuberculosis**

Other forms of tuberculosis, such as lymphatic, pericardial, gastrointestinal, cutaneous, skeletal, and genitourinary, may be either coincidental findings or may provide clues to the diagnosis of disseminated disease in critically ill patients [11].

Tuberculosis patients on therapy may also present to the ICU after developing an immune reconstitution syndrome or paradoxical reaction. This syndrome is characterized by a worsening of symptoms and/or radiographic studies despite effective chemotherapy with microbiologic improvement [63]. Typical manifestations are the recurrence or development of fever and other systemic manifestations, enlargement and suppuration of lymphatic tissue, worsening of pulmonary infiltrates, and life-threatening complications such as respiratory failure or enlargement of intracranial lesions. These reactions can occur in any tuberculosis patient but are most common in patients with tuberculosis and HIV coinfection who are started on ART within the first few months of tuberculosis treatment [64].

**Chest Radiography**

Routine chest radiography is an invaluable screening and diagnostic tool for patients at risk for tuberculosis. Radiographs are able to detect most active pulmonary tuberculosis cases, particularly the most infectious cases with extensive parenchymal disease and cavitation. Radiographs can demonstrate fibrosis from previously active tuberculosis that identifies patients at higher risk for reactivation and can provide clues to the diagnosis in patients with extrapulmonary disease. The classic radiographic appearance of active tuberculosis is a fibrotic, cavitary upper-lobe opacity (Fig. 82.1), but pulmonary tuberculosis can present with a variety of findings on chest radiograph, including a normal film. The radiographic appearance of tuberculosis depends primarily upon the duration of illness and the host’s immune function. For example, primary tuberculosis typically presents as a lower lobe infiltrate often with ipsilateral hilar adenopathy. Primary tuberculosis occurs most often in young children but can be seen at any age including the elderly, as described among recently infected nursing home residents [65]. Other radiographic appearances, which can be seen alone or in combination, are alveolar opacities, mixed alveolar-interstitial infiltrates, miliary disease, and intrathoracic adenopathy (Figs. 82.2 and 82.4) [8]. These “atypical” presentations of pulmonary tuberculosis have been reported in
up to 34% to 45% of HIV-negative individuals in some series [66,67]. In the presence of advanced immunodeficiency, there is greater variation in the radiographic patterns of tuberculosis with more frequently lower lobe involvement, diffuse infiltrates, hilar or mediastinal adenopathy, and pleural effusions [52,68].

FIGURE 82.4 Chest radiographs of a 49-year-old patient who had undergone a liver transplant 6 months prior for hepatitis B–associated liver disease. The initial radiograph (A) showed right paratracheal adenopathy (arrow) with partial right lower lobe collapse that resolved by the end of treatment (B). The patient received standard tuberculosis therapy with the substitution of rifabutin for rifampin to minimize the drug interaction with tacrolimus.

Tuberculin Skin Testing and Interferon-γ Release Assays

The tuberculin skin test (TST) had been the only licensed test for detecting tuberculosis infection, but newer blood tests, interferon-γ release assays (IGRAs), are now commercially available [11,69]. IGRAs measure the interferon-γ produced by peripheral blood lymphocytes after stimulation with mycobacterial antigens. Both the TST and IGRAs are useful adjunctive tests but must be interpreted with caution. A positive result indicates the patient has been infected and may increase your clinical suspicion for active disease but is nondiagnostic. Similarly, a negative test does not rule out active tuberculosis since between 10% and 25% of patients with culture-confirmed disease will have a negative TST or IGRA [70,71].
Nucleic Acid Amplification Tests

Culture remains the gold standard for diagnosing all forms of tuberculosis, although it is limited by the duration of growth needed to identify *M. tuberculosis*. One approach to overcome these limitations has been the development of nucleic acid amplification (NAA) tests [72]. These tests offer several advantages including a rapid result, high specificity, and broad application to tissue samples, in some cases even formalin-fixed tissue [73]. The “first generation” of these tests were limited by a sensitivity of approximately 50% for smear-negative pulmonary, pleural, and meningeal tuberculosis [61,74]. Later-generation NAA tests such as Gene Xpert MTB/RIF and Line Probe assays can identify tuberculosis in <24 hours on either smear-negative or smear-positive sputum specimens. Current guidelines for the use of nucleic acid tests published by the Centers for Disease Control and Prevention (CDC) are to perform NAA testing on at least one specimen from individuals in whom TB remains high on the differential and where the result would alter management [75]. The sensitivity of these more recently developed NAA tests is greater than 95% in smear-positive specimens but only 50% to 80% in smear-negative, culture-positive specimens [76–79]. Importantly, these NAA tests not only determine if a specimen contains *M. tuberculosis*, but also give information about drug resistance. In individuals who have previously been treated for tuberculosis or who are from countries with a substantial amount of drug resistance, this information is critical to designing tuberculosis treatment regimens. Rapid susceptibility testing is most important for identifying *M. tuberculosis* isolates with resistance to at least isoniazid and rifampin. These isolates are referred to as multidrug resistant because tuberculosis due to these strains can be expected to fail standard therapy [80].

Rifampin susceptibility or resistance is determined by the *rpoB* gene, making it the most accurate target for molecular testing. Line probe assays utilize DNA probes to amplify genetic mutations that then undergo reverse hybridization with probes that can detect both rifampin and isoniazid resistance [81]. The MTBDRplus (Hain Lifescience) detects resistance to isoniazid and rifampin, whereas MTBDRsl can detect resistance to fluoroquinolones, aminoglycosides/cyclic peptides, and ethambutol, with good correlation to culture-based drug susceptibility testing [82]. Probes using molecular beacons such as GeneXpert MTB/RIF TB assay (Cepheid) will emit light when tuberculosis is present and can detect rifampin resistance [34]. Similar to sputum smears, a negative NAA test does not exclude tuberculosis. Therefore, empiric treatment should be considered when an alternative diagnosis has not been made, there is no clinical improvement, and the patient is at risk for tuberculosis.
Culture and Drug Susceptibility Testing

The importance of using rapid diagnostic techniques in clinical mycobacteriology has been tragically illustrated in outbreaks of drug-resistant tuberculosis among immunocompromised hosts whose median survival with standard, ineffective therapy was 16 days [3]. Liquid culture systems containing radiometric or colorimetric material permit detection of mycobacterial growth in 2 to 6 days with an average of 2 weeks [83]. The traditional use of biochemical testing for identification of isolates as *M. tuberculosis* has been largely replaced by the more accurate and rapid methods using commercial nucleic acid probes. Drug susceptibility testing can also be done more rapidly with the commercial liquid cultures systems. Many hospital laboratories now lack the expertise and the number of specimens to conduct the full range of testing on a daily basis [11]. More timely results may be achieved by sending specimens, particularly those that are AFB smear positive to a full-service mycobacteriology laboratory. It is critical to pair molecular testing for resistance with standard phenotypic culture-based drug susceptibility testing, to ensure that resistance mediated through mutations not detected through NAA testing are also identified.
TREATMENT

Principles of Therapy for Tuberculosis

Two characteristics of *M. tuberculosis* dictate the requirements for successful therapy: a high frequency of spontaneous mutations and a slow, intermittent growth cycle. Overcoming these characteristics requires multiple drugs to prevent the selection of drug-resistant mutants and an extended duration of therapy to kill the dormant mycobacteria [80]. Culture confirmation should always be pursued aggressively, but empiric therapy for tuberculosis based on clinical suspicion should be considered and may be important for the survival of critically ill patients.

Recommendations for Initial Therapy

The choice of initial tuberculosis therapy in the ICU should be made after considering the risk for multidrug-resistant disease. The potential for drug-resistant tuberculosis can be estimated by knowing the patient’s country of birth and whether he or she has a history of prior tuberculosis treatment. In 2013, the percentage of patients with multidrug-resistant tuberculosis among U.S.-born and foreign-born persons with no prior tuberculosis treatment was low at 0.3% and 1.7%, respectively. Among those with a history of prior treatment, these rates increased to 2.2% in U.S.-born and 5.1% in foreign-born persons [84]. Drug resistance should also be suspected for patients who fail while on treatment or who relapse after treatment has ended, particularly patients who did not get directly observed therapy [85,86].

For most patients, the four-drug, oral regimen of isoniazid, rifampin, pyrazinamide, and ethambutol will be appropriate [80]. The choice of therapy, when drug resistance is suspected, should be made in consultation with a physician experienced in treating multidrug-resistant tuberculosis and generally should include two or more agents likely to have activity. The agents usually chosen include an aminoglycoside (amikacin, kanamycin, or capreomycin), a fluoroquinolone (typically levofloxacin or moxifloxacin), and one or two of the “second-line” agents such as ethionamide, cycloserine, or *p*-aminosalicylic acid (PAS) [80,87]. Of note, ethambutol-pyrazinamide, ethionamide, cycloserine, and PAS can only be given orally, and of these all except PAS can be given enterally via a feeding tube because PAS can clog enteral feeding tubes [80,87]. Due to the relatively poor antituberculosis activity of second-line drugs, some experts have recommended measuring serum drug levels to allow dose increases in order to achieve concentrations above the in vitro minimum
inhibitory concentration [88]. Although not examined in a comparative trial, surgical resection may be a useful adjunct in the therapy of multidrug-resistant tuberculosis after weeks or months of medical therapy [87].

More detailed information regarding tuberculosis treatment is available on the CDC website (http://www.cdc.gov/tb/publications/guidelines/Treatment.htm). Other complicating factors that may need consideration when starting tuberculosis therapy in a critically ill patient are shown in Table 82.2.

### TABLE 82.2 Select Therapeutic Challenges in Treating Critically Ill Tuberculosis Patients (When Drug-Susceptible Disease Is Known or Expected)

1. Documented or anticipated malabsorption—medications that can be given parenterally
   a. Rifampin
   b. Fluoroquinolone—levofloxacin or moxifloxacin
   c. Aminoglycoside—amikacin (streptomycin can be used if drug susceptibility is known); second-line agents are kanamycin and capreomycin
   d. Isoniazid—when available but it may be difficult to obtain as a parenteral medication
   e. Linezolid

2. Hepatic failure—acute or severe
   a. Empiric therapy: aminoglycoside, fluoroquinolone (levofloxacin may be preferred since moxifloxacin is hepatically cleared), ethambutol, (consider including rifampin if not fulminant hepatic failure)
   b. Avoid: isoniazid and pyrazinamide

3. Renal failure
   a. Dose adjust: ethambutol, pyrazinamide, aminoglycosides, and levofloxacin
   b. No change in dosing: isoniazid, rifampin, linezolid, and moxifloxacin

4. Pregnancy
   a. Empiric therapy: isoniazid, rifampin, ethambutol. Pyrazinamide is generally avoided in the United
States; however, use in pregnancy is recommended by WHO [103], particularly in severely ill individuals with underlying HIV disease. Therefore, its use should be considered in pregnant women with severe disease or who are immunocompromised.

b. Avoid: aminoglycosides and if possible, limit the use of fluoroquinolones given limited data for their use in pregnancy

### Adjunctive Corticosteroids

In certain circumstances, corticosteroids may be useful for adjunctive tuberculosis treatment by reducing the intensity of the inflammatory response [80]. In a randomized, placebo-controlled trial, corticosteroids were shown to lower the mortality and morbidity of patients with tuberculous meningitis [89]. Corticosteroids also reduce the need for pericardiocentesis in patients being treated for tuberculous pericarditis [90], but there does not appear to be a long-term benefit in reducing the late complication of constrictive pericarditis. Corticosteroids also appear beneficial for treating severe pulmonary tuberculosis with more rapid defervescence, weight gain, and radiographic improvement [91]. The initial corticosteroid dose in most studies has been the equivalent of 40 to 80 mg of daily prednisone, tapering off over 1 to 3 months.

### Management of Adverse Drug Effects

During the treatment of tuberculosis, serious mistakes can result from the failure to appropriately recognize and manage adverse drug effects [92]. Most mistakes fall into three categories: (1) failing to discontinue therapy in the face of a serious adverse effect; (2) abandoning important first-line drugs because of minor adverse effects; and (3) failing to recognize serious drug–drug interactions. Drug-induced hepatitis is probably the greatest concern for clinicians treating tuberculosis, particularly when patients have underlying liver disease. Fortunately, the risk of fulminant hepatitis is low and generally occurs when tuberculosis medications are continued despite evidence of toxicity.

While clinically significant or fulminant hepatitis is rare, increased transaminase levels are common with the combination of isoniazid, rifampin, and pyrazinamide. Clinicians should also remember that
patients with severe or disseminated tuberculosis might have elevated liver function tests, particularly alkaline phosphatase, as a result of their disease. Patients with abnormal liver function tests and no known cause should have tuberculosis treatment held if transaminases are three times the upper limit of normal and the patient has symptoms of toxicity (i.e., nausea, vomiting, loss of appetite, or jaundice) or if transaminases are five times the upper limit in asymptomatic patients [93]. Patients with underlying liver disease and/or baseline liver function abnormalities should generally start standard tuberculosis treatment with close monitoring of symptoms and liver function tests.

The decision to stop or change therapy due to liver dysfunction must be made on a case-by-case basis. When therapy is held due to hepatotoxicity, the drugs are usually restarted cautiously, resuming one drug at a time. Pyrazinamide is the most frequent cause of liver injury in patients receiving the standard four-drug regimen and may best be avoided if rifampin and isoniazid are reintroduced without difficulty. Among critically ill patients for whom holding therapy may pose a significant risk, reasonable short-term therapy can be achieved with an aminoglycoside, fluoroquinolone, and ethambutol (Table 82.2). Patients who develop a rapid rise in transaminases to levels of 10 to 20 times normal should probably not be rechallenged with pyrazinamide or isoniazid. Other serious side effects that should result in the permanent discontinuation of the offending medication are severe rifampin-associated hypersensitivity reactions like acute renal failure, hemolysis, or thrombocytopenia.

When minor side effects occur, all attempts should be made to treat the symptoms and to determine if an alternative cause exists before discontinuing standard first-line tuberculosis medications. Minor side effects such as gastrointestinal upset can often be managed by adjusting the dosing schedule or by prescribing an antiemetic. Isolated bilirubin elevation caused by rifampin-associated cholestasis may occur but resolves despite continued therapy. Transient minor rashes or pruritus are often associated with pyrazinamide and may be managed using antihistamines without interrupting therapy.

Finally, recognizing potentially serious drug–drug interactions and adjusting therapy accordingly can avoid many drug-associated adverse events. Rifampin and to a lesser extent rifabutin are inducers of the hepatic cytochrome P-450 enzyme system. Therefore, particular caution should be used when HIV-infected tuberculosis patients are taking or may be starting ART [94]. The optimal timing for antiretrovirals has been controversial, but three recent trials have greatly improved our understanding of when to start ART in individuals with tuberculosis [95–98]. When initiating ART for individuals with CD4 counts <50 cells per µL, there was a mortality benefit to initiating after 2 weeks of
tuberculosis treatment despite the higher risk of immune reconstitution syndrome in this group. Otherwise, there was no mortality benefit to delaying the initiation of ART to near the end of the initial 8-week phase of tuberculosis treatment. However, the optimal timing of ART in highly immunosuppressed individuals with CNS disease is uncertain, but early therapy in one trial did not show a benefit [99].

Updated recommendations for the combined use of tuberculosis and HIV drugs can be found on the CDC website at (http://www.cdc.gov/tb/publications/guidelines/TB_HIV_Drugs/default.htm. Other notable interactions with rifamycins include warfarin, most antiseizure medications, and many antirejection medications given for bone marrow and solid-organ transplants. The safest practice is to review all medications when treating someone with a rifamycin.
INFECTION CONTROL AND RESPIRATORY ISOLATION

Preventing Nosocomial Transmission

Early suspicion for tuberculosis is the most important step in preventing transmission because it allows the appropriate use of effective respiratory isolation, prompt diagnostic evaluation, and initiation of effective treatment. Screening for active tuberculosis is generally achieved through the collection of three sputa for AFB smear. In 2015, the Food and Drug Administration (FDA) approved use of Xpert MTB/RIF to evaluate for tuberculosis within hospitalized patients because a recent study demonstrated that the negative predictive value of 1 to 2 Xpert tests is high [100]. However, pulmonary tuberculosis with smear-negative disease is transmittable, and although data are limited, the potential exists for transmission to occur in tuberculosis patients who are Xpert negative and culture positive [101]. Therefore, hospitalized patients with negative sputum smears or negative Xpert testing but are at high risk for tuberculosis should be kept in respiratory isolation until an alternative diagnosis is made or empiric TB treatment has been initiated for several days. The infectiousness of tuberculosis begins to decrease within days after initiating effective therapy, probably by decreasing the cough as well as by reducing the number of tubercle bacilli. Decisions about discontinuing isolation once treatment is instituted should be carefully individualized considering the initial burden of disease and the clinical and microbiologic response to treatment, avoiding a decision based only on the number of days on therapy. Other measures that may be of benefit in intubated patient include the use of a closed suctioning system to avoid generating infectious aerosols and the use of submicron filters for air exhausted from ventilators [38].

All health care workers who will be exposed to potentially infectious tuberculosis patients should use personal protective devices. Properly fitted masks capable of filtering at least 95% of particles 1 μm in size are recommended with fit-testing to ensure a face-seal leakage of less than 10%. Powered air-purifying respirators with a helmet or hood are a more effective and more expensive option. These could be considered for certain high-risk situations such as an unavoidable bronchoscopy of an infectious case of tuberculosis. Periodic tuberculin testing or IGRA testing [102] of hospital personnel should be continued as a means of monitoring the effectiveness of other measures and of evaluating tuberculin converters and providing treatment when appropriate [38].
Public Health Aspects

Presumptive and confirmed cases of tuberculosis should be promptly reported to the local public health department as required by law in every state. The function of this reporting is to provide the opportunity to conduct timely contact investigations, which may be critical to preventing life-threatening complications of tuberculosis among small children or immunocompromised household members. In addition, many health departments can assist in ensuring completion of outpatient therapy and thus prevent a hospital readmission for treatment failure or relapse with drug-resistant tuberculosis.

Treatment recommendations for tuberculosis, based on randomized controlled trials, are summarized in Table 82.3.

TABLE 82.3 Summary of Recommendations for Tuberculosis Treatment That Are Supported by Randomized Controlled Trials

</table>

Adjunctive corticosteroids are recommended for:

| 1. Tuberculous meningitis—improved survival and fewer serious adverse events [89] |
| 2. Tuberculosis pericarditis—there is no improved survival with the routine addition of corticosteroids for pericardial TB", however corticosteroids may be considered in individuals who have large effusions or who are unable to undergo a pericardial window [90] |

13. Lillebaek T, Dirksen A, Baess I, et al: Molecular evidence of

There are a number of established, emerging, and reemerging viruses that can lead to severe respiratory illness in immunocompetent individuals. The etiologic agents of serious viral pneumonias can generally be divided into three groups:

1. **Human-adapted respiratory viruses.** The primary site of entry, replication, and disease for these viruses is the human respiratory tract. They are spread efficiently by person-to-person transmission. The most significant members of this group are the human influenza A and B viruses; others are respiratory syncytial virus (RSV) and adenovirus.

2. **Human-adapted viruses—respiratory disease after a viremic phase.** Viral entry and person-to-person spread of these viruses are via the respiratory tract. However, these viruses cause respiratory illness after a phase of systemic viral replication and dissemination. Members of this group include varicella zoster virus (chickenpox) and rubeola virus (measles).

3. **Zoonotic viruses.** Viruses in this group include the New World hantaviruses producing the hantavirus cardiopulmonary syndrome (HCPS), H5N1, and other avian influenza A viruses, and the severe acute respiratory syndrome (SARS) coronavirus.

**PATHOGENESIS**

A virus must first gain access to the lower respiratory tract in order to produce severe pneumonia. The most common mode of entry is via droplet transmission. Airborne virus-containing droplets 5 to 10 μm in
diameter are filtered and deposited in the upper respiratory tract. Virus reaches the lower respiratory tract after efficient replication and spread within squamous epithelial cells, often in the setting of impaired mucociliary clearance (due to extremes of age, antecedent or concurrent infections, and drugs). This is the usual mode of entry for many human-adapted respiratory viruses, such as influenza, RSV, adenovirus, and coronavirus. Person-to-person spread via droplets is limited to a distance of approximately 1 m. Other viruses such as varicella and rubeola are transmitted via aerosols (particles 1 to 5 μm in diameter) that can deposit directly in the lower respiratory tract. As such, they are highly infectious and can be transmitted over greater distances and time than agents transmitted by droplets. Although deposited directly in alveoli, viral dissemination to the lung typically occurs hematogenously after a viremic phase [1,2].

Once in the lower respiratory tract, there are a limited number of ways that the lung can respond to a viral infection and produce respiratory illness. Viral invasion and replication can directly produce a necrotizing bronchopneumonia with highly inflammatory, purulent, and exudative reactions. This is not common, but can be seen with influenza and adenovirus infections. Respiratory viral infections can impair host lung defenses in a way that leads to secondary bacterial pneumonias, particularly with *Streptococcus pneumoniae* or *Staphylococcus aureus*. The classic examples are postinfluenza or measles pneumonias. Finally, viral infection of the lower respiratory tract may produce severe disease by triggering a common tissue response to acute lung injuries termed *diffuse alveolar damage* or *acute respiratory distress syndrome*. The acute lung injury may progress from an early exudative phase, often with profound noncardiogenic pulmonary edema (especially in HCPS); to a proliferative or organizing phase that produces interstitial inflammation, and a late resolving phase [3].
CLINICAL MANIFESTATIONS

The limited host-response patterns to virus-induced lung injury mean that there is significant overlap of the clinical manifestations of viral pneumonias. The clues to a specific viral etiology are often found in assessing host risk factors and epidemiology on presentation. A summary of the common clinical manifestations for specific viral pneumonias is presented in Table 83.1. Many of the viral infections discussed in this chapter are characterized by a “flu-like illness” prodrome. Symptoms begin with the acute onset of headache, chills, and myalgias. Within a few days, a cough and sore throat develop along with upper respiratory tract infection. The presence or absence of upper respiratory symptoms at this stage may provide one clue to the specific viral etiology. The human-adapted respiratory viruses (human influenza, RSV, adenovirus, and non-SARS coronavirus) generally all produce upper respiratory symptoms. Measles is characterized by coryza and conjunctivitis in the prodrome. The absence of upper respiratory symptoms has been reported to be characteristic of infections with several of the zoonotic viruses: SARS coronavirus, hantaviruses, and H5N1 and other avian influenza viruses [4–6]. The lower respiratory tract signs and symptoms in viral pneumonias are generally nonspecific and progress to dyspnea, tachypnea, and inspiratory crackles (rales). Sputum production is variable. If the clinical course is biphasic (dyspnea and productive cough after improvement of a flu-like illness), then a secondary bacterial pneumonia should be suspected.

</table>
Incubation period is 10–20 d after infection

Risk factors for developing pneumonia:
- nonimmune adults
- smoking
- chronic obstructive pulmonary disease
- >100 skin lesions
- pregnancy, third trimester

**Rubeola virus**
- Epidemic transmission, localized outbreaks in household and community settings
- Outbreaks in doctor’s offices and emergency departments
- Infectivity greatest in the 3 d before onset of rash in index case (incubation period 10–14 d)
- Risk factors for severe illness: nonimmune adults and children <5 y old; crowding; pregnancy; HIV infection; malnourished children, developing countries; vitamin A deficiency

**Prodrome:** cough, coryza, conjunctivitis
- Unilateral and bilateral primary viral pneumonia
- Secondary bacterial pneumonias (S. pneumoniae, S. aureus, and others)

**SARS coronavirus**
- Epidemic/outbreak settings
- Originated in Asia
- Person-to-person transmission after contact with symptomatic, SARS CoV-infected person
- No transmission seen since 2003

**Fever,** myalgias, cough
- Upper respiratory signs/symptoms are uncommon
- Dyspnea, tachypnea, respiratory decompensation develop around second week of illness

**Watery diarrhea** in 25% of patients around second week of illness

**Fomite and direct contact with respiratory droplets**
- Airborne: aerosol transmission

**Epidemic transmission, fomite and direct contact with respiratory droplets**
- Airborne: aerosol transmission

**SARS-CoV** transmission (≥10 μm)
- Fomites

**Originated in Asia**
- Person-to-person transmission after contact with symptomatic, SARS CoV-infected person
- No transmission seen since 2003
New World hantaviruses | Small-particle aerosols generated from rodent excreta | Sporadic, clustered cases in Americas Exposure to rodents, their droppings and urine, especially in closed spaces In general, no person-to-person transmission (except possibly with Andes virus) | Febrile/flu-like prodrome usually without any upper respiratory signs/symptoms Rapid progression to noncardiogenic pulmonary edema/ARDS with hypotension

Avian influenza A viruses (e.g., H5N1) | Presumed droplet transmission and/or direct contact from bird to human | Sporadic cases in countries with animal influenza A H5N1 Close contact/exposure to live or dead domestic fowl or wild birds or domestic ducks Few reports of limited person-to-person transmission by intimate contact only | Flu-like prodrome often without upper respiratory signs/symptoms Early development of primary viral pneumonia

ARDS, acute respiratory distress syndrome; CNS, central nervous system; HIV, human immunodeficiency virus; SARS CoV, severe acute respiratory syndrome coronavirus.

Routine laboratory tests are generally of little help in distinguishing among the viruses that can produce severe respiratory illness. Total leukocyte counts are typically within the normal range or slightly elevated. One exception is measles virus infection, which can produce a marked leukopenia [7]. The most common hematologic finding in the viral pneumonias is a relative lymphopenia. The complete blood count may be useful for diagnosing HCPS. In HCPS caused by Sin Nombre virus (a New World hantavirus), the triad of thrombocytopenia (platelet count less than 150 K per mm$^3$), absolute neutrophilia, and the presence of immunoblasts was a sensitive and specific predictor of HCPS in one study [5]. Electrolyte abnormalities and hepatic transaminase elevation can occur among any of the severe viral pneumonias.

The radiographic findings of the viral pneumonias are also broad and
nonspecific. Radiographic infiltrates can have interstitial, alveolar, or combined patterns. The presence of only a diffuse alveolar pattern might suggest primary influenza pneumonia with hemorrhagic alveolitis [8] or the capillary leak syndrome of acute respiratory distress syndrome, especially due to HCPS. Peribronchial nodular infiltrates is a pattern often reported with varicella pneumonia [9]. Computed tomography (CT) scans are better at detecting the presence, extent, and complications of respiratory infections than chest radiographs. However, they are no better at defining particular radiographic patterns of specific viral or bacterial causes [9].
DIAGNOSIS

The diagnostic modalities available for viral pneumonias rely on the detection of a viral component (nucleic acid or protein), growth of the virus in vitro, or development of a virus-specific antibody response. Definitive serologic evidence of a viral infection requires a rise in virus-specific antibody titers between paired acute illness and convalescent sera. With a few exceptions, serologic assays are therefore not generally helpful for the clinician in the acute setting of a severe viral pneumonia. This section will focus on diagnostic tests that may assist the clinician faced with a critically ill patient and suspected viral pneumonia.

Human Influenza A and B

Rapid, direct, antigen-detection assays are commercially available for diagnosing human influenza A and B virus infections. These assays rely on detection of the influenza virus nucleoprotein in respiratory secretions, and results can be obtained within 1 hour. Because they are based on the viral nucleoprotein, none of the rapid antigen tests provide information about influenza A hemagglutinin subtypes (e.g., H1, H3). Details regarding the available rapid antigen tests for influenza are provided by the Centers for Disease Control and Prevention (CDC) (http://www.cdc.gov/flu/professionals/diagnosis/rapidclin.htm). The test specificities for diagnosing an influenza virus infection are generally high (more than 90%), but reported sensitivities are lower (33% to 80%) and may vary for different human influenza A virus subtypes [10–12]. In clinical practice, the timing and method of sample collection can greatly affect test sensitivity. Influenza A virus shedding from the upper respiratory tract typically peaks 2 to 3 days after symptom onset [13,14]. The window available to reliably detect viral antigen from upper respiratory tract secretions may extend only 5 to 6 days after symptom onset. Influenza virus nucleoprotein is most abundant in the columnar respiratory epithelium. Posterior nasopharyngeal swabs or aspirates that collect columnar epithelial cells are usually the preferred samples for rapid antigen detection assays [10,15,16], even for mechanically ventilated patients in the intensive care unit (ICU).

Reverse transcriptase polymerase chain reaction (RT-PCR) assays and viral cultures are the next most commonly used diagnostic tests for human influenza virus infections. Posterior nasopharyngeal swabs or washes, and samples of lower respiratory tract secretions such as endotracheal aspirates or bronchoalveolar lavages, are acceptable
samples. Virus typing and influenza A subtyping can be accomplished with either method. Due to its high sensitivity, specificity, and throughput, RT-PCR assays have generally supplanted virus culture in most clinical microbiology laboratories. Unlike viral culture, the detection of influenza viral RNA by RT-PCR cannot assess the presence of live virus in respiratory secretions.

**Respiratory Syncytial Virus (RSV)**

Rapid antigen-detection assays and direct immunofluorescent staining for RSV from respiratory secretions have been the primary diagnostic tests used in children. These tests have >80% sensitivity and >90% specificity [17]. RT-PCR assays and respiratory viral culture are the other common diagnostic approaches in pediatric populations. Among adults, the RSV rapid antigen assays and viral cultures are generally insensitive due to low virus shedding and preexisting anti-RSV antibody in respiratory secretions [18,19]. Direct fluorescent antibody staining in nasopharyngeal specimens was reported to be the only rapid assay at least equivalent to viral culture in adults [17]. A RT-PCR assay on respiratory secretions is the preferred acute illness diagnostic method for RSV infection in adults [20,21].

**Adenovirus**

PCR of adenovirus DNA or respiratory viral culture from a nasopharyngeal swab or aspirate, sputum, or lower respiratory tract secretions is the diagnostic test of choice for adenoviral pneumonia. Direct adenovirus antigen assays that cover most serotypes, such as immunofluorescent antibody staining, are not as sensitive as PCR assays or viral culture.

**Varicella**

Varicella pneumonia typically develops within 1 to 6 days after the characteristic rash of chickenpox has appeared [22]. If desired, a specific microbiological diagnosis can be obtained by PCR assay or viral culture from a swab or scraping at the base of an unroofed vesicle. Viral detection in respiratory secretions is generally not required.

**Rubeola (Measles)**

Pulmonary involvement with measles is generally diagnosed on the basis of history and physical findings. In outbreak settings, pneumonia should be suspected for patients who develop respiratory distress and persistent or recurrent fevers during the course of typical measles. Measles is
characterized by malaise and fever, followed rapidly by coryza, conjunctivitis, and cough [23]. Early in illness, the presence of Koplik spots on the buccal mucosa is pathognomonic of measles. The classic morbilliform rash begins 3 to 4 days after onset of illness and starts to fade after another 3 days. Worsening respiratory symptoms as the rash is fading is suspicious for rubeola pneumonia. Laboratory confirmation may be useful, particularly for suspected sporadic cases within a highly immunized population. Viral isolation or rapid detection of measles antigen in nasopharyngeal secretions is difficult and not readily available. A presumptive serologic diagnosis can be made by detection of serum anti-measles virus immunoglobulin M (IgM) or immunoglobulin G (IgG) in unimmunized individuals. Serum antibodies appear 1 to 3 days after onset of the rash [24]. Definitive serologic diagnosis requires paired acute and convalescent sera. In immunocompromised patients with overwhelming pneumonia, the antibody response may be minimal. Viral antigen staining of cells or RT-PCR assays on nasal exudates or urinary sediment may be useful in this setting [23].

Severe Acute Respiratory Syndrome (SARS) Coronavirus

The most practical diagnostic approach for SARS coronavirus is a RT-PCR assay on nasopharyngeal specimens within 2 weeks after symptom onset [25]. The other primary site where SARS coronavirus RNA can be detected is stool (week 2 onward). Lower respiratory tract secretions harbor a greater viral load than upper respiratory tract secretions early in illness. However, lower respiratory tract aspiration, lavage, or intubation pose serious nosocomial transmission risks and should not be pursued solely for diagnostic purposes. IgM seroconversion does not occur until after the first week of illness and therefore is also of limited diagnostic utility [4]. With resolution of SARS viral transmission in 2003, and the apparent subsequent mutation of the virus [26], any initial positive test for SARS coronavirus must be viewed as a potential false-positive finding. Middle Eastern Respiratory Syndrome (MERS) is another coronavirus associated with transmission by camels. This virus and its manifestations are discussed in Chapter 84.

Hantaviruses

There are nearly a dozen New World hantaviruses that have been associated with HCPS. Sin Nombre virus (in the southwestern United
States) and Andes virus (in South America) are the two best known HCPS-associated hantaviruses. The diagnosis of HCPS can be made by detection of anti-hantavirus IgM antibodies in acute illness serum. Nearly all patients with HCPS have detectable IgM in their sera at the onset of pulmonary edema. The currently available IgM capture enzyme-linked immunosorbent assay using a recombinant Sin Nombre virus antigen can be used to diagnose all New World hantavirus infections [27]. RT-PCR assay on blood or lung tissue is a research assay of limited utility and not widely available. Because of low yield and biosafety issues, attempted culture of hantaviruses in clinical microbiology laboratories is not recommended.

**Avian Influenza Viruses (e.g., H5N1)**

If H5N1 influenza A virus infection is suspected on epidemiologic grounds, then all avenues for making a definitive diagnosis should be pursued. The diagnostic approach to H5N1 influenza is to collect nasopharyngeal and lower respiratory tract specimens for rapid antigen detection, RT-PCR assay, and viral culture. Aerosol-generating procedures for specimen collection should be performed with appropriate infection control precautions. Detection of viral RNA in respiratory specimens by RT-PCR is the most sensitive and rapid method for detecting influenza A/H5N1. A hallmark of H5N1 influenza has been a higher frequency of virus detection and viral loads in pharyngeal and lower respiratory tract samples than in nasal samples between 2 and 16 days after the onset of illness [6,28]. Viral RNA has also been detected in fecal samples. The CDC has provided guidance for the laboratory testing of suspected H5N1 and other avian influenza cases (http://www.cdc.gov/flu/avianflu/). The clinical microbiology laboratory should be notified, if H5N1 or another avian influenza A virus infection is suspected and specimens are collected for viral culture. This is to ensure that the specimens will be handled and processed with the appropriate biosafety containment level.
TREATMENT AND MANAGEMENT

Caring for a patient with a severe viral pneumonia can be complex; however, the approach to such a patient is often identical to that of other acute severe pneumonias. First, a clinical assessment of disease severity is made so that an appropriate level of care can be established. This process can be assisted by standardized scoring algorithms established for critically ill patients or community-acquired pneumonias [29,30]. Supportive care with maintenance of ventilation, oxygenation, and hemodynamic parameters is based on general principles previously outlined in Chapter 181. Next, diagnostic procedures to try to establish the cause of the severe pneumonia can be pursued. Finally, one needs to evaluate the role of specific antiviral and/or immunomodulatory therapies in the care of the patient. As with most infectious pneumonias, the decision to treat with these therapies is often made empirically or with limited diagnostic information. A summary of potential therapeutic options, dosages, and adverse effects is presented in Table 83.2.

### TABLE 83.2 Summary of Antiviral Agents and Therapeutic Options for Specific Viral Pneumonias

**Human Influenza A and B**

There are two classes of antiviral drugs currently available for the treatment of human influenza virus infections: adamantanes (amantadine and rimantadine) and neuraminidase inhibitors (oseltamivir, zanamivir, and peramivir). The adamantanes are older, established compounds, but they are not active against influenza B. In placebo-controlled trials, when amantadine or rimantadine therapy was
initiated within 48 hours of symptom onset in influenza A virus infections, there was a 1-to-2-day reduction in duration of fever and overall illness symptom scores [31]. However, there are no controlled data on the utility of adamantanes in the treatment of severe influenza A lower respiratory tract infections, and several factors make them less than ideal for patients in the ICU. In several studies, rimantadine treatment produced small initial decreases in viral titers, but later in therapy, similar or higher frequencies of viral shedding compared with placebo [32]. The incidence of adamantane resistance among influenza A viruses has increased in recent years [33]. Resistance emerges at a high frequency during treatment with adamantanes, and resistant virus can be transmitted to the close contacts of patients in community and nosocomial settings [32,34].

The neuraminidase inhibitors have activity against influenza A and B. As with the adamantanes, oseltamivir and zanamivir decrease the duration and severity of generalized symptoms by approximately 1 day when started within 48 hours after onset of illness [35]. Some lines of evidence make the neuraminidase inhibitors attractive for treatment of patients with severe influenza virus pneumonias. They markedly reduce viral load during the first 48 hours of treatment, can decrease viral shedding, and may lower the incidence of influenza-related lower respiratory tract complications [36–38]. However, the latter benefit has been questioned by a meta-analysis [39]. Development of resistance to oseltamivir or zanamivir has been uncommon in immunocompetent adults, but appears to be higher in children and immunocompromised individuals [40,41]. Importantly, person-to-person transmission of resistant virus has not been documented. Zanamivir may be active against some oseltamivir-resistant strains.

Despite the lack of randomized controlled trials in the ICU setting, most practitioners would initiate treatment with a neuraminidase inhibitor in patients with suspected or confirmed severe influenza pneumonia. Recent trials have not identified a clinical benefit of higher (double) dose oseltamivir [42,43]. Zanamivir should not be nebulized for patients on mechanical ventilation due to possible obstruction of the ventilation circuit (http://www.fda.gov/safety/medwatch/safetyinformation/safetyalertsforhumanmedicalproducts/ucm186081.htm Peramivir is an intravenous neuraminidase inhibitor.

Pregnant women, infants, and children younger than 2 years, individuals with chronic cardiopulmonary or renal disease, and those immunosuppressed were at higher risk of developing severe illness during the 2009 H1N1 influenza pandemic (same as in all human influenza outbreaks). The 2009 H1N1 virus has become the dominant circulating influenza A H1N1 strain worldwide. There are no data to support the use of corticosteroids in the treatment of influenza
pneumonia, and inhaled ribavirin is not beneficial [44]. An important addition to the treatment of influenza pneumonia is antibacterial therapy. There is a high incidence of secondary bacterial infections complicating influenza pneumonia, particularly with *S. pneumoniae* or *S. aureus* [45]. In this setting, antibiotic therapy directed against *S. aureus* should be added to the antibiotic regimen used for community-acquired pneumonia bacterial pathogens. In areas where there is a high prevalence of community-acquired methicillin-resistant *S. aureus*, vancomycin should be used as the initial antistaphylococcal antibiotic.

**Respiratory Syncytial Virus**

Because respiratory syncytial virus (RSV) is a frequent cause of serious lower respiratory tract infections among infants and young children, data on potential therapies come from pediatric studies. There have been no trials of anti-RSV therapies in adults. The current treatment strategies for RSV lower respiratory tract infections are essentially supportive. Aerosolized ribavirin therapy of infants with RSV lower respiratory tract infections had no significant effects on clinical outcome in two randomized trials [46,47]. Palivizumab, a humanized anti-RSV neutralizing monoclonal antibody, has been successful in reducing hospitalizations of high risk children for RSV lower respiratory tract infections when given prophylactically [48]. However, the utility of palivizumab or anti-RSV immune globulin as a potential treatment of serious RSV infections is unknown. Clinical observations and a mouse model of RSV infection have demonstrated airway hyperresponsiveness and other asthmatic changes in RSV-infected lungs [49], and prompted trials of anti-inflammatory therapies. Unfortunately, two randomized trials failed to demonstrate any overall beneficial effect of intravenous dexamethasone in RSV lower respiratory tract infections [50,51]. On subgroup analysis in one study, dexamethasone treatment was beneficial in mechanically ventilated patients with bronchiolitis and mild gas exchange abnormalities (PaO$_2$/FIO$_2$ more than 200 mm Hg or mean airway pressure $\leq$10 cm H$_2$O) [50]. These findings have yet to be confirmed in a prospective fashion.

**Adenovirus**

Adenoviral pneumonia occurs in isolated outbreaks among immunocompetent adults or sporadically in immunocompromised individuals. As such, there are no prospective randomized trials of
antiviral medications. Cidofovir is an antiviral drug with potent in vitro activity against adenovirus. Cidofovir has been reported to be successful for treating adenoviral pneumonia in small case series [52–54], and is currently considered the antiviral agent of choice. Because severe adenovirus disease is associated with defects in cellular or humoral immunity, donor lymphocyte infusions, and intravenous immunoglobulin have been used as adjunctive therapy [52]. Their efficacy for the treatment of adenoviral pneumonia is unknown.

Varicella

Intravenous acyclovir is considered standard therapy for the treatment of varicella pneumonia. There have been no randomized controlled trials of acyclovir for varicella pneumonia. Its efficacy for reducing the severity of pox lesions [55,56] and apparent benefit in numerous case series of varicella pneumonia support its use. A compilation of 46 case reports and 227 patients with varicella pneumonia suggested that mortality was 3.6-fold higher in untreated compared with acyclovir-treated patients [22]. In a small uncontrolled retrospective study, patients who received adjunctive corticosteroids had shorter ICU and hospital stays than those who did not receive corticosteroids [57]. There are no prospective controlled studies supporting the use of adjunctive corticosteroid therapy in varicella pneumonia.

Rubeola (Measles)

Pneumonia is the most common severe complication of measles and accounts for most measles-associated deaths [58]. There is no specific antiviral therapy for measles. In developing countries, treatment with vitamin A has been associated with a 50% reduction in the mortality of severe measles. Hospitalized children with measles in the United States often have a measurable deficiency in vitamin A, and they are more likely to have pneumonia or diarrhea. The World Health Organization recommends vitamin A therapy for all children with measles, and the American Academy of Pediatrics recommends vitamin A therapy for hospitalized children older than 2 years with measles in the United States [58]. Data for older children and adults are lacking, but vitamin A treatment should probably be provided for all individuals with severe measles [59,60]. Intravenous ribavirin was reported to have beneficial effects in a small case series of measles pneumonia in adults [61], but there are no data from prospective randomized studies. Another important point in the treatment of measles pneumonia is antibacterial therapy. Secondary bacterial pneumonia and laryngotracheobronchitis are frequent complications of measles. As with influenza, S. aureus and S. pneumoniae are the most commonly isolated bacterial pathogens. Less
frequent bacterial causes of pneumonia following measles include *Neisseria meningitidis*, *Klebsiella pneumoniae*, *Escherichia coli*, *Haemophilus influenzae*, and *Pseudomonas* species [58]. Broad-spectrum antibiotic therapy, including coverage for *S. aureus* and *S. pneumoniae*, should be instituted.

**Severe Acute Respiratory Syndrome (SARS) Coronavirus**

The SARS epidemic of 2003 was marked by the empiric use of several antiviral and immunomodulatory strategies because controlled trials were not possible. Ribavirin was the most commonly used antiviral agent, but its poor in vitro activity against the SARS coronavirus and its apparent limited ability to reduce early viral shedding in patients makes its usefulness questionable [62]. Corticosteroids were used extensively during the SARS outbreak of 2003 at varying doses and durations. Retrospective analyses on the effects of corticosteroids in SARS suggest that they did not provide any significant benefits and may have been associated with some adverse outcomes [62,63].

**Hantaviruses**

There has been only one placebo-controlled, double-blind trial of intravenous ribavirin for the treatment of HCPS due to Sin Nombre virus [64]. The accrual of study subjects was low and inadequate to clearly assess the efficacy of ribavirin. There were no trends to support the use of ribavirin in patients presenting in the cardiopulmonary phase of HCPS. Whether ribavirin may have a beneficial effect if initiated during the prodromal phase is unknown. Intravenous ribavirin was beneficial when given early to patients with another hantavirus disease, hemorrhagic fever with renal syndrome caused by Hantaan virus [65]. There is no evidence that pharmacologic doses of corticosteroids provide any benefit in HCPS.

At the present time, clinical management of HCPS involves supportive care with several caveats. Excessive fluid resuscitation will exacerbate the pulmonary edema of HCPS without commensurate improvement in cardiac output. Recommendations are to fluid resuscitate with 1 to 2 L of isotonic crystalloid and then maintain as low a wedge pressure (8 to 12 mm Hg) as is compatible with satisfactory cardiac output (cardiac index more than 2.2 L/min/m²). The use of loop diuretics is discouraged. Inotropic agents (e.g., dobutamine, dopamine, and norepinephrine) should be initiated earlier in resuscitation than in other conditions, instead of continued fluid boluses [5].
Avian Influenza Viruses (e.g., H5N1)

The H5N1 influenza A viruses are susceptible in vitro to the neuraminidase inhibitors, and neuraminidase inhibitors have been protective in animal models of influenza A H5N1 infection [66–68]. Although prospective clinical trials have not been performed, the current recommendation is that patients with suspected influenza A H5N1 infection promptly receive a neuraminidase inhibitor, preferably within 48 hours of infection [6,69]. Emergence of resistance to oseltamivir has been documented in a few patients with H5N1 infections treated with oseltamivir [70]. These strains remain susceptible to zanamivir. Whether combination therapy with zanamivir or other antivirals is beneficial and would reduce the emergence of oseltamivir resistance is unknown. The influenza A H5N1 isolates from Asia are highly resistant to the adamantanes, and therefore these drugs do not play a therapeutic role [6]. Corticosteroids have been used in the treatment of sporadic influenza A H5N1 infections, but their routine use cannot be recommended. In a randomized trial in Vietnam, all four patients given dexamethasone died [71].
INFECTION CONTROL ISSUES FOR THE INTENSIVE CARE UNIT

Most of the viruses presented in this chapter can be transmitted in the nosocomial setting via direct contact with an infected patient and through inhalation of droplets or aerosols. Efforts to reduce transmission to healthcare workers and other patients are often guided by the transmission efficiency of the specific viral agents. Human influenza, RSV, adenovirus, varicella, and measles are efficiently transmitted person to person. SARS coronavirus and avian influenza A H5N1 virus are transmitted less efficiently, but nosocomial transmission may be promoted by aerosol-generating procedures. The New World hantaviruses are generally not transmitted person to person, except possibly the Andes virus.

Strategies to prevent nosocomial transmission include isolation precautions for patients, chemoprophylaxis and immunization of healthcare workers if possible, and surveillance and rapid identification of healthcare workers’ exposures. In general, patients with suspected epidemic viral pneumonias should be housed with a combination of standard, contact, droplet, and airborne isolation precautions. When feasible, limit the number of healthcare workers with direct access to the patient and limit their contact with other patients. Restrict visitors to a minimum and provide them appropriate personal protective equipment. High-efficiency N-95 masks or powered air-purifying respirators are preferred for healthcare workers. If high-efficiency masks are limited or unavailable, surgical masks may be considered if the primary mode of agent transmission is via droplets and no aerosol-generating procedures are performed. Detailed guidelines can be found on the CDC Web site (http://www.cdc.gov/ncidod/dhqp/guidelines.html).

Advances of antiviral or immunomodulatory therapy of viral pneumonias based on randomized controlled trials or meta-analyses of such trials is summarized in Table 83.3.

<table>
<thead>
<tr>
<th>TABLE 83.3 Summary of Recommendations for Antiviral or Immunomodulatory Therapies of Viral Pneumonias Based on Randomized Controlled Clinical Trials</th>
</tr>
</thead>
<tbody>
<tr>
<td>Human influenza</td>
</tr>
</tbody>
</table>
• Neuraminidase inhibitors given within 48 h of flu symptom onset decrease the duration of symptoms, viral load, and viral shedding; controversy as to whether they lower the incidence of influenza-related lower respiratory tract complications [35,39]; no randomized controlled trials for treatment of severe pneumonia.
• Aerosolized ribavirin does not provide any clinical benefit [44].

**Respiratory syncytial virus (RSV)**

• Aerosolized ribavirin has no significant effect on outcome in infants with RSV lower respiratory tract infections [46,47].
• Intravenous dexamethasone does not provide any overall beneficial effect in RSV lower respiratory tract infections [50,51].
• On post-hoc analysis, dexamethasone (0.6 mg/kg IV q6 h × 48 h) may be beneficial in mechanically ventilated patients with bronchiolitis and mild gas exchange abnormalities (PaO$_2$/FIO$_2$ > 200 mm Hg or mean airway pressure ≤ 10 cm H$_2$O) [50].

**Adenovirus**

• No randomized controlled trials of cidofovir for adenovirus pneumonia.

**Varicella**

• No randomized controlled trials of IV acyclovir for varicella pneumonia. A meta-analysis of published case series suggests that IV acyclovir decreases mortality [22].

**Rubeola (measles)**

• Oral vitamin A therapy decreases mortality and improves recovery from pneumonia in children [58,59].

**SARS coronavirus**

• No randomized controlled trials for antivirals or corticosteroids.
Hantavirus cardiopulmonary syndrome (HCPS)

- No trends to support the use of ribavirin in patients presenting in the cardiopulmonary phase of HCPS [64].

Avian influenza A viruses (e.g., H5N1)

- Neuraminidase inhibitors have been protective in animal models of influenza A H5N1 infection. There are no patient-based randomized controlled trials.
- No trends to support the use of dexamethasone from a small, unpublished, randomized trial [71].

IV, intravenous; SARS, severe acute respiratory syndrome.

CORONAVIRUSES ARE IMPORTANT EMERGING PATHOGENS

The Coronaviridae are a family of viruses that infect a wide-range of animal species, including humans. Coronaviruses (CoV) are large positive-sense RNA viruses. The virion is enveloped with cellular membrane and is formed of the virus-encoded structural proteins, of which spike (S) protein is the main attachment factor responsible for entry of the virion into the host cell [1]. Of the known human coronaviruses (hCoV), all cause respiratory tract infections of varying severity. There are a number of less pathogenic coronaviruses, namely hCoV-229E, hCoV-HKU1, hCoV-OC43, and hCoV-NL63, that cause common-cold–like symptoms in healthy adults, though all of these coronaviruses have been associated with more severe diseases in particularly susceptible populations, such as those with immune deficiencies, the young or the elderly [2,3]. However, since 2003 there have been two incidences of highly pathogenic coronaviruses in humans, emerging from zoonotic reservoirs: severe acute respiratory syndrome (SARS)-CoV and Middle East respiratory syndrome (MERS)-CoV, which cause severe respiratory infections that can lead to lethal disease in previously healthy adults [4,5].

SARS-CoV was the first identified coronavirus that developed into highly lethal severe respiratory tract infection. The first confirmed case was in November 2002, after which it spread around the world to 26 countries, causing 8,096 confirmed cases and 774 deaths (a case fatality
rate of 9.6%) [4,6]. The last reported community-acquired infection was in July 2003 because SARS-CoV was eventually controlled by effective quarantine of infected persons and elimination of the direct animal reservoir. During the SARS-CoV epidemic, therapy for severe cases was restricted to standard respiratory support and there were, and still are not, any approved treatments or vaccines for specific use against SARS-CoV [7].

All known human coronaviruses, except for hCoV-229E, have strong evidence of a zoonotic origin. SARS-CoV emerged in 2003 in the Guangdong province of China from Chinese horseshoe bats of the Rhinolophidae family [8] and passed into humans via raccoon dogs and civet cats [9] in the wet markets of China, where all of these species interact with each other.
EMERGENCE OF MERS-CoV

In November 2012, the first report of MERS-CoV infection in humans was of a case that presented with severe respiratory infection in July 2012 [5]. As of March 2016, MERS-CoV has spread to 27 countries, causing 1,625 confirmed cases and 585 deaths (a case fatality rate of 36%; www.who.org). It was suggested that the high case fatality rate was due to underreporting of asymptomatic or mild MERS-CoV infection; however, large-scale screens of populations of the Middle East have so far failed to show large numbers of people exposed to MERS-CoV [10].

The vast majority of MERS-CoV cases are in the Middle East, in particular the Kingdom of Saudi Arabia, and most cases reported outside of the Middle East are in people who travelled to the Middle East, became infected with MERS-CoV and then returned home prior to developing symptoms, resulting in small numbers of case reports in countries such as the United States [11]. There is evidence of human-to-human transmission of MERS-CoV, though community-acquired MERS-CoV infections do not appear to be a significant aspect of MERS-CoV transmission. However, once in a hospital setting with many comorbid patients, MERS-CoV spreads efficiently, causing lethal disease as well as asymptomatic cases, including healthy adults.

A prime example of the transmissibility of MERS-CoV was a recent outbreak in the Republic of Korea (ROK) in 2015 [12]. In ROK, a patient travelled to the Middle East became infected with MERS-CoV and then returned home to Seoul. After returning home, he fell ill and became patient 0 in the outbreak that occurred there. Once symptoms developed, the patient travelled through the ROK medical system, and it has been possible to track the spread of MERS-CoV through other patients and medical staff in that system [13,14]. The ROK outbreak eventually caused a total of 186 confirmed cases and 33 deaths, none of whom, other than patient 0, had any other recent travel to the Middle East. This suggests that human-to-human transmission can and does occur when there is close and sustained contact with a MERS-CoV–infected individual [15].

There is evidence that MERS-CoV exists in bat populations in the Middle East, particularly the Egyptian tomb bat (Taphozous perforates) [16], and, therefore, this is the ultimate reservoir of MERS-CoV. There is also evidence that dromedary camels (Camelus dromedaries) act as an intermediate between bats and humans [17,18]. Camels are an extremely important species in the Middle East, where they are a source of meat, fabric, and milk, and camel racing is an important part of the cultural and economic development in the region.
MERS-CoV RECEPTOR USAGE AND TROPISM

The cell surface receptor for MERS-CoV has been identified as dipeptidyl peptidase-4 (DPP4) [19]. DPP4 is a promiscuous enzyme with a wide-range of substrates, including cytokines [20], growth factors [21], and incretins such as glucagon-like protein 1 (GLP1) [22]. DPP4 is widely expressed in many organs, but levels of expression vary, even within an organ. DPP4 is expressed in the human respiratory tract [23], in particular in alveolar epithelial cells (both type I and type II), alveolar macrophages and less so in the upper respiratory tract [23]. This suggests that MERS-CoV has a particular affinity for the lower respiratory tract, the site usually associated with more severe respiratory infections. Interestingly, DPP4 in the lower respiratory tract was shown to be unregulated in patients with chronic lung diseases [23], suggesting that there are conditions that can predispose a patient to a higher burden of pulmonary MERS-CoV infection.

DPP4 is also highly expressed in the kidney [24], kidney cells are susceptible to MERS-CoV infection in vitro [25] and individual case reports have reported kidney problems as a result of MERS-CoV infection, including in the first reported MERS-CoV infection [5]. There is also in vitro evidence that MERS-CoV can infect circulating T cells [26], which suggest that MERS-CoV can be found in the blood. However, there is currently no evidence of direct infection by MERS-CoV of any cell outside the lung during human infections.

The interaction between the MERS-CoV S protein and DPP4 is highly dependent on the posttranslational modification of DPP4. Mice cannot be infected with MERS-CoV [27] and it has been shown that mouse DPP4 is not a functional receptor for MERS-CoV [28], because mouse DPP4 contains a glycosylated residue that conflicts with MERS-CoV S binding [29].
MERS-CoV CLINICAL SYMPTOMS AND RISK FACTORS

After a predicted incubation period of 5 to 14 days [30], severe MERS-CoV–induced disease typically begins with fever, cough, chills, sore throat, myalgia, and arthralgia that progresses to pneumonia that often requires mechanical ventilation of other support within the first week (Table 84.1) [31]. Though respiratory symptoms are the major feature of MERS-CoV infection, some patients also develop gastrointestinal symptoms, such as vomiting or diarrhea [31] and there is evidence that MERS-CoV RNA can be isolated from blood, urine and stool of infected patients [32]. Furthermore, there are suggestions that kidney failure was a result of MERS-CoV infection, including in the first reported case [5] and epidemiological analysis has shown a correlation between MERS-CoV and kidney failure [33,34], however, it remains unclear if this is a direct result of MERS-CoV replication in any organ outside the lung, or is a result of the multi-organ failure caused by a severe pneumonia.

Information in this table is derived from a review of MERS-CoV–associated symptoms [31].

There has only been a single autopsy report of a fatal human MERS-CoV infection [35]. The lungs displayed extensive damage, with diffuse alveolar damage, denuding of the bronchiolar epithelium and type II pneumocyte hyperplasia [35]. There is also evidence of edema and the alveolar septa were thickened with lymphocytes (but not plasma cells),
neutrophils, and macrophages [35]. The authors also observed damage to other organs, such as the kidney and spleen, but did not observe any MERS-CoV antigen or RNA in these areas [35], suggesting that these features were not a direct result of MERS-CoV infection and may also be due to an extended time from death to autopsy.

Direct exposure to dromedary camels is a risk factor for developing MERS-CoV infection [36], which further suggests that camels, or animals closely linked to them, are the intermediate reservoir of MERS-CoV. Epidemiological studies of risk factors for developing severe symptoms of MERS-CoV infection have suggested that comorbidities have a strong correlation with severe MERS-CoV infection (Table 84.2) [34,36,37]. In particular, preexisting diabetes is strongly associated with a more severe outcome from MERS-CoV infection [34]. Some have suggested that age is a factor in severe MERS-CoV infection [37]; however, others have not shown a strong correlation [34] and age may be a factor only in the sense that other comorbidities increase with age. Later analyses have suggested that there is no significant association between severe MERS-CoV and gender [34,37], despite data occasionally showing a significant correlation between severe MERS-CoV disease and being male [38,39] that were most likely a result of external factors, such as males usually being responsible for handling camels and therefore more exposed to MERS-CoV [36,39].

Information is this table is derived from epidemiological analyses of MERS-CoV risk factors and comorbidities [34,36,37]. Each factor in the table has been associated with MERS-CoV in at least one of these studies. Gender, specifically being male, is excluded from the table, as this factor has been specifically identified with access to dromedary camels [36,39].
ISOLATION OF INFECTED PATIENTS AND CONTAINMENT OF SECRETIONS

Because human-to-human transmission does occur, isolation of infected patients in isolation rooms with negative pressure is recommended. All medical staff attending to suspected MERS-CoV–infected patients should wear personal protective equipment to protect against transmission, including gowns, gloves, and face shield or goggles that are either disposable or able to be cleaned with disinfectants [40]. Additionally, all equipment used on MERS-CoV–infected patients should be thoroughly sterilized, or disposed of in a fully contained waste receptacle after use and patients who need to leave isolation should wear the same protective equipment as the medical staff [40]. It is also important to establish a clear infection control plan for use in the hospital setting, including rapid diagnostic and safety protocols [41].
TREATMENTS FOR MERS-CoV

There are currently no approved treatments or vaccines for MERS-CoV and use of antivirals to treat MERS-CoV is limited to advisory opinions for the most severe cases (Table 84.3) [42]. There have been no specific guidelines issued on the use of specific supportive therapies, such as steroids, colloid, or electrolytes for MERS-CoV–associated pneumonia; however, any therapy with immunosuppressive activity should be used with care in MERS-CoV–infected patients, as this may exacerbate the disease.

In vitro screens of FDA-approved compounds have identified a number
of inhibitors of MERS-CoV [43,44], but none has been tested in human clinical trials as a treatment for MERS-CoV infection. A number of small-scale trials, however, have been attempted in severe cases of MERS-CoV using treatments that show efficacy against other viruses. Ribavirin and type I interferons (IFN) have been shown to be effective against viruses such as hepatitis C virus [45] and in an animal model of MERS-CoV infection [46]. Therefore, these have been used for a small number of cases to attempt to treat MERS-CoV. A retrospective study suggested that treatment with ribavirin and IFN-α2a correlated with enhanced survival at 14 days posttreatment, though not at 28 days posttreatment [47], however, as acknowledged by the authors themselves, the sample size was low and there have been no placebo controlled trials of this combination in the treatment of MERS-CoV. Additionally, in at least one study, use of ribavirin and IFN-α2b was shown to have no effect on outcome of MERS-CoV infection [48]. In a third study, two patients were also treated with ribavirin and IFN-α2b. The first patient developed respiratory symptoms and was treated with ribavirin and IFN-α2b at first symptom development, 72 hours before being shown to be MERS-CoV positive by RT-PCR. This patient recovered and was discharged. The second patient, the wife of the first, was given ribavirin and IFN-α2b prophylactically and developed respiratory symptoms, but was never MERS-CoV RT-PCR positive. This patient also recovered and was discharged. In total, these studies suggest no effect of ribavirin and IFN-α2b and potentially a worse outcome from this treatment. Interestingly, ribavirin and IFN-α2b treatment is still being used in KSA and further analysis of larger cohorts of patients is forthcoming. No other treatments are currently approved for use in MERS patients.

Novel treatments designed to specifically inhibit MERS-CoV are still in the very early stages of development, but several have shown promise in vitro and in animal models. However, none of these have yet entered clinical trials and, therefore, are some time away from being used in clinics to treat MERS-CoV infection.
REFERENCES

Ebola virus disease (EVD), a severe illness caused by various strains of the filovirus Ebola, represents a major concern for critical care units in resource-rich settings not only because of the lethality of the infection but also because of issues pertaining to infection control, resource allocation, and treatment ethics. EVD had previously been confined to small outbreaks in Central Africa; however, the West African Outbreak that began in 2014 ultimately spread to ten countries on three different continents and affected more than 10 times the number of people from all previous Ebola outbreaks combined [1]. The size and worldwide nature of this outbreak demonstrates that health care facilities require protocols for the care of patients who might be or are definitively harboring Biosafety Level 4 agents such as Ebola.

The following chapter will review special considerations for the diagnosis and care of patients with Ebola virus infection. Given its similar taxonomy and clinical features, the principles discussed here almost certainly apply in like manner to patients suffering from Marburg virus disease, which since its original episode in Germany has not been observed outside of sub-Saharan Africa, but is equally likely to present off the African continent given the ease and increase of international travel.

**EPIDEMIOLOGY AND PATHOGENESIS**

There are four principal strains of the virus that are known to cause virus in humans: Zaire (ZEBOV), Sudan (SEBOV), Bundibugyo (BDBV), and Taï Forest (TAFV), the last of which has only had one known human case [2]. ZEBOV and SEBOV outbreaks are associated with a significantly higher mortality rate (approximately 50% to 90%) than BDBV (approximately 25%) [3,4]. A fifth strain, the Reston Ebolavirus (RESTV),
has thus far not been associated with human disease, although antibody responses of humans exposed to the virus have been observed [5].

The transmission of Ebola primarily takes place by direct contact with body fluids, where virions enter into the host via mucous membranes or skin breaks [6]. Ebola virus has been detected in virtually every body fluid [7]. The virus has now been shown to persist for months in semen, effectively making EVD a sexually transmitted disease well past the time when outbreaks have traditionally been considered to have run their course [8]. Parenteral introduction of the virus, such as seen with needlestick exposures, often cause severe disease and represent a major hazard for medical personnel caring for patients with EVD in high-resource settings [9].

Incubation of the virus typically lasts between 2 and 21 days; most cases present in the second week following exposure [10]. The relatively long incubation times coupled with highly efficient transcontinental travel underscores the importance of heightened surveillance and the need for health care facilities everywhere to have response plans in place. Of the four cases of Ebola diagnosed in the United States, two had acquired the virus in Africa [11]. Therefore, patients from Ebola-endemic countries presenting with circulatory collapse in the setting of a febrile illness may require rapid isolation and testing for Ebola and Marburg.

The bulk of pathophysiologic studies have been performed on nonhuman primates (NHPs) in Biosafety Level 4 facilities; the presentation of EVD in NHPs is similar to that of humans and the fatality rate is likewise similar [12]. NHP studies have demonstrated that significant disruption of the endothelial and epithelial barriers of the colon takes place, leading to diffuse mucosal injury and inflammation [13]. This, in turn, may lead to gut translocation of gram-negative organisms, potentially leading to bacterial sepsis as a major cause of mortality [14]. Moreover, the cytokine cascade induced by EVD (which includes a complex interplay of TNF-α, IL-1-β, IL-6, IL-10, and various interferons) probably produces intravascular coagulation and may account for the hemorrhage of EVD cases when hemorrhage occurs [15].
CLINICAL PRESENTATION

EVD typically presents initially as a viral prodrome with nonspecific symptoms, making clinical diagnosis essentially impossible except in large outbreaks. The overwhelming majority of patients present with fever [16]. Some previous studies have noted that body temperatures in EVD can fluctuate [17]. Other common early symptoms include fatigue, arthralgias and myalgias, anorexia, headache, and abdominal pain. A diffuse, erythematous nonpruritic maculopapular rash was only rarely reported in the West African Outbreak, although it appeared to have been more prevalent among the whites who became infected and thus may have been underdiagnosed in Africans with darker skin [18].

Confirmation of EVD is done via reverse transcription polymerase chain reaction (RT-PCR). Because the test may not be positive in the early stages of the illness, a patient with suspected EVD and a negative RT-PCR test less than 72 hours after onset of symptoms does not necessarily rule out infection. If the patient is no longer symptomatic after 72 hours, repeat testing is not required; however, patients with ongoing symptoms must be retested. Similarly, if a patient with symptoms greater than 72 hours in duration tests negative, EVD is ruled out.

Laboratory values in the setting of EVD resemble those of other acute viral illnesses, with common findings including leukopenia (with or without atypical lymphocytosis), thrombocytopenia, transaminitis (AST > ALT), hyponatremia, hypocalcemia, elevated creatinine, elevated lactate, hypoalbuminemia, and prolonged prothrombin time (PT) and partial thromboplastin time (PTT) values. Potassium regulation can be difficult, as one study indicated that equal numbers of patients developed hypo- or hyperkalemia [19]. As with symptoms of EVD, pathognomonic clinical signs do not exist, although a pulse-temperature dissociation similar to that seen in typhoid fever has been observed, and a saddleback fever curve has also been reported for some patients. Hiccups may also be seen and should prompt suspicion in the setting of other appropriate epidemiologic clues [20].

EVD is primarily a gastrointestinal syndrome that can cause massive fluid losses. For instance, during the West African Outbreak an epidemiologist working for the WHO became infected and was flown to Germany on the 10th day after onset of symptoms; the patient was recorded to have total fluid losses of nearly 10 L per day, mainly in the form of diarrhea and, to a smaller extent, vomiting [21]. Coupled with insensible losses from fevers, the significant fluid depletion often leads to circulatory collapse and likely accounts at least in part for the high
mortality of the disease.

Despite its reputation as a disease with a massive bleeding diathesis, EVD does not typically present with frank hemorrhage. The prevalence of bleeding of any kind before the West African Outbreak was reported to be in the range of approximately 50%; during the West African Outbreak, at least one study reported a prevalence of less than 20% [22]. Studies in previous outbreaks indicated that, although less common, hemorrhage was typically associated with a worse prognosis [23]. Similarly, mental status changes such as encephalopathy probably reflects end-organ damage and carries a high mortality. The clinical presentation, laboratory symptoms, and prognostic factors associated with EVD are summarized in Table 85.1.

Survival and convalescence are prolonged. While many patients
experience rapid improvement, they remain viremic for as long as 21 days or more [24]. Therefore, provisions need to be made for convalescing patients who must remain in isolation during this time, and psychosocial needs may outweigh physiologic considerations, as survivors commonly cope with fear, grief, and anxiety about the social stigma that may await them following discharge [25]. Current WHO guidelines for discharge is that the patient meet the criteria of having no signs and symptoms of EVD, as well as two negative Ebola PCR tests on whole blood separated by at least 48 hours [26].

Following discharge, patients experience a range of complications that can be debilitating and last for months or even years. These complications are summarized in Table 85.2. The persistence of Ebola virus in immunologically privileged “sanctuary” sites, such as semen [27] and ocular fluid [28], indicates that special precautions must be taken when evaluating survivors in routine follow-up care, with Biosafety Level 4 protocols being used in the event that providers might be exposed to fluids from these viral reservoirs.

INFECTION CONTROL AND OTHER SAFETY CONSIDERATIONS

The management of patients with EVD must be carried out with maximum adherence to infection control procedures and health care worker safety considerations. In critical care settings, the need for safety protocols is even greater due to the larger number of opportunities for occupational exposure.

If faced with the care of a patient with suspected or confirmed EVD, health care facilities should have a specialized, fully trained team of health care workers assigned to such patients. The team would include all personnel whose work is necessary in intensive care settings. Periodic training and “dry run” simulations should be considered, especially due to the physically demanding nature of Ebola care brought on by the sensory deprivations of personal protective equipment (PPE).

The Centers for Disease Control and Prevention (CDC) recommends standard, contact, and droplet precautions for isolation of and care for patients with suspected or known EVD [29]. PPE should ensure the health care worker has no skin exposed. Donning and doffing should always take place in a single decontamination area that is clearly demarcated. Only staff involved in entering or leaving the high-risk area, or those who are supervising such workers, should be allowed in such areas. The entry and exit process should proceed according to a strict step-by-step protocol provided by either the CDC or WHO. Owing to the multistep nature of the donning and doffing procedures, the protocol should be simulated multiple times by the staff. Before entering a high-risk area, the health care worker should have their PPE examined for any exposed areas. Special care should be given to evaluation of the face if goggles are being worn on top of a hood instead of a single headpiece, as the corners of the mask may not overlap.

Perfect adherence to protocol during doffing in particular is critical because this is when the outer surface of PPE may be coated in virus, and protocol deviations place health care workers at possibly the highest risk of exposure. Multiple disinfection steps with bleach solution are essential. Doffing should be supervised by a trained observer who calls out each step of the protocol. If the worker “gets lost” in the multistep process, the supervisor/observer should always spray the worker down with a bleach solution before proceeding to the next step.

Once inside a high-risk area, the care of patients with EVD proceeds as it would with any other patient. Because standard PPE in EVD care typically involves two layers of gloves, special care should be taken to any
tasks requiring fine motor skill, such as IV line placement (either peripherally or centrally), hooking and unhooking IV lines, withdrawing blood for laboratory analysis, and so on.

Currently, there is controversy as to whether EVD can be transmitted through aerosols, and whether negative pressure rooms are completely necessary is a topic of debate at the time of this writing. A statement by the WHO notes that there have been no documented cases of aerosolized transmission of Ebola [30], but other specialists counter that this may be possible given findings in animal models of EVD [31]. Consequently, PPE should include either N95 respirators or powered air purifying respirators. The latter, while more expensive, have the advantages of not requiring fit testing and may provide better protection in the event of splashes.

Laboratory testing presents a special challenge in Ebola care. Because commonly tested body fluids used in clinical specimens should be regarded as highly infectious and require at least as much care with respect to decontamination as health care workers, testing should be minimized to the greatest extent possible. Point-of-care testing, when possible, should be utilized, particularly as clinical Ebola management involves monitoring and adjusting standard laboratory parameters, especially sodium and potassium, for which point-of-care products are generally found with ease.

Health care workers identified for work in a high-risk area with suspect or confirmed EVD cases should be considered candidates for Ebola vaccines if they are available. At present, multiple candidate vaccines have been studied, although no definitive results with respect to vaccine efficacy have been established at the time of this writing [32]. Consultation with CDC or WHO health officials should take place immediately in confirmed EVD cases to assess the availability of vaccines for health care staff planning on caring for such patients [33].
Supportive care, while not having any direct action against the Ebola virus, almost certainly has a significant impact on mortality. Of the many thousands of cases of EVD in the West African Outbreak, 24 were treated in Western countries, with five deaths, which represented a much lower case fatality rate than those infected in Africa. Moreover, of the 7 EVD cases whose symptoms began in the West, only one patient died, and this patient’s diagnosis was delayed [34]. Although nearly all of these patients underwent experimental therapies, the fact that they were all provided supportive care as a single common denominator, coupled with the much lower mortality rates both in the current outbreak and in the past, indicates that such care is critically important.

Empiric antibiotics may be beneficial. As noted previously, NHP models indicate that EVD causes a massive inflammatory response in the gut mucosa, potentially leading to translocation of gut organisms and ultimately bacterial sepsis late in the course of EVD infection. Therefore, institution of broad-spectrum antibiotics may have a mortality impact. Although no definitive clinical data exist to support this, one observational study of 581 patients with EVD in Sierra Leone in 2014 showed a lower case fatality rate compared with the overall rate; all such patients were given intravenous ceftriaxone along with oral metronidazole for the first 72 hours following admission to the Ebola Treatment Unit. Coupled with the pathophysiologic studies of NHPs, the Sierra Leone data suggest that empiric broad-spectrum antibiotics should be instituted at the time of diagnosis and continued for a minimum of 72 hours [35].

No randomized trials have been performed on the value of intravenous access in EVD. However, the evidence available strongly supports the idea that parenteral access is likely to have at least a moderate, and possibly profound, favorable impact on patient care. One review concluded that the ability to infuse large volumes of fluid in order to counteract the intravascular collapse brought on by EVD is likely to yield significant benefits with respect to morbidity and mortality. If routine intravenous access cannot be obtained, intraosseous or even subcutaneous routes could be considered viable alternatives [36]. Once fluid repletion is instituted, care should be given to frequent monitoring of electrolyte levels, particularly sodium and potassium, whose values can fluctuate dramatically. There is no evidence for which crystalloid solution is superior (e.g., normal saline vs. Lactated Ringer’s).

Less is known about other tools in the arsenal of critical care medicine, such as intubation and hemodialysis, as effectively the entire literature on
these interventions is limited to case reports [37,38]. Still, the evidence would suggest that patients should be treated for sepsis syndrome with such technologies provided the risk to health care providers is sufficiently minimized. Noninvasive mechanical ventilation is not a recommended strategy due to the possibility of aerosolized transmission.

Other supportive care measures include antipyretics, antiemetics, and analgesics. Antipyretics should favor acetaminophen over nonsteroidal anti-inflammatory drugs (NSAIDs) due to nephrotoxicity of the latter as well as antiplatelet effects, although dosage adjustments must be considered on the basis of hepatic function. Antimotility agents are controversial because the benefits of fluid retention are balanced by the risks of translocation of gut organisms that could result in gram-negative septicemia, which has been documented in at least one case report. If the patient became infected in a malaria-endemic region, then evaluation for and treatment of malaria is indicated [39].
SPECIFIC THERAPY

In the absence of approved treatments for EVD, during the West African Outbreak, multiple drugs were provided under compassionate-use doctrines with the goal of decreasing the mortality of the disease. Favipiravir, an oral medication used for influenza and that has been shown to have anti-Ebola activity both with in vitro and in vivo models [40], was administered in a Phase II study in Guinea, but the study was fraught with numerous experimental design flaws, preventing a comprehensive assessment of its value [41].

Unlike the “repurposed” drug favipiravir, TKM-Ebola was designed specifically with EVD treatment in mind. TKM-Ebola is a cocktail of three small interfering (si)RNA molecules intended to disrupt viral replication, transcription, assembly, and evasion of the host immune response. The drug was found to be effective in a nonhuman primate model, preventing death in 100% of animals following a lethal challenge [42]. A Phase I trial was launched during the West African Outbreak, but was put on partial hold following the discovery of high cytokine release in the study subjects [43]. It was administered under compassionate-use protocols for two other patients, both of whom survived, but their reactions during infusions (including fevers, rigors, and a general health decline) make it difficult to assess its clinical value [44].

The monoclonal antibody mixture ZMapp is designed to neutralize the virus by binding to discrete regions of the surface glycoprotein. As with TKM-Ebola, ZMapp was shown to be effective in a nonhuman primate model. However, large-scale production of ZMapp proved challenging, and its use was mainly limited to compassionate-use instances in the West. Generally, patients fared well, but other intensive care measures may have been primarily responsible for the low mortality [45]. However, a clinical trial of ZMapp in West Africa has just been completed as this book is going to press, and results should be available by its publication [46].

Two novel therapeutic approaches were not studied in humans during the West African Outbreak, but are being investigated in animal models. First, antisense oligonucleotides, referred to as “PMOs” (phosphorodiamidate morpholino oligomers) have been evaluated in Phase I trials and appear to be safe [47]. Second, the nucleoside analog BCX4430 is designed to act as a viral RNA chain terminator, and studies are ongoing as to its feasibility in humans [48].

In situations where the above drugs have not been scaled up for mass production, as well as in resource-limited settings, the use of convalescent whole blood or convalescent plasma may be considered if
EVD survivors are available for donation. This strategy has been used in previous EVD outbreaks, although concerns about alloimmunization, febrile transfusion reactions, graft-versus-host disease, and other side effects would suggest this approach be considered as second-line at best [49]. Furthermore, infection control procedures surrounding the donation, manipulation, and infusion of survivor blood products, but done while minimizing the amount of equipment required in a BL-4 setting, make fast implementation a major challenge and thus may create more problems than they solve.
The challenges of intensive care of patients with EVD not only is limited to the technical matters described above, but also impact the relationship between patient and provider, for the occupational exposure risks involved in end-of-life situations (such as cardiopulmonary resuscitation) raise the question of just how much should providers be obligated to do in such circumstances. Although no clear consensus exists at this time as to whether or not certain heroic measures can be jettisoned for EVD care, current guidelines of critically ill patients already account for the need to individualize goals of care [50], and in this respect EVD is simply one factor in the decision-making process. When possible, medical staff responsible for the care of patients with EVD should discuss with one another potential scenarios that could reasonably be postulated and how team members will react in such instances. Mobilization of a hospital ethical committee for the express purpose of considering these matters also has the potential to prevent misunderstandings so that all providers have uniform expectations of their roles and the roles of their colleagues.
AUTHOR DISCLOSURE

The author has served as a paid consultant by Medivector, Inc., which produces the drug favipiravir and is discussed in this review.

5. Yadav S, Rawal G: The current mental health status of Ebola survivors

Botulism remains a rare disease but a potential threat to many people across the world. Recognition of the disease is important as it is life-threatening and treatable. Early recognition and prompt treatment improves outcomes and are essential to initiate surveillance for other potential cases in an outbreak or bioterrorism event.

The name botulism is derived from the Latin term *botulus* for sausage. Justinus Kerner (1786 to 1862) first recognized the association between the mysterious “sausage poison” and paralytic illnesses in 1820. *Clostridium botulinum*, the etiologic agent of botulism, is an anaerobic, spore-forming organism that elaborates a neurotoxin that prevents the release of acetylcholine. Genetic studies have revealed heterogeneity of the organisms containing the botulism toxin genes indicating that traditional forms of nomenclature defining the organism by the presence of the toxin gene or gene product are too simplistic. Currently, the organisms that carry the gene and produce the toxin are divided into four subspecies and two related species. This helps to explain why the toxin is seen in environments beyond the traditional loamy soils where potatoes and other vegetables implicated in outbreaks are grown [1].

Illness develops after toxin exposure, and patients present with a symmetric descending paralysis that characteristically begins with dysarthria, diplopia, dysphonia, or dysphagia. The most common botulism syndromes include food-borne, wound, and infant botulism. Botulism toxin is also now used therapeutically in neuromuscular and ophthalmologic disorders as well as a cosmetic enhancement tool, and cases of iatrogenic botulism have occurred. Although the majority of cases are due to infant botulism, food-borne botulism is considered a public health emergency, as there is always a potential that a large number of individuals may have been exposed. Additionally, *botulinum* is a category A biological agent, and any case must initially be considered as
potentially linked to a bioterrorist event (see Chapter 130).

PATHOGENESIS

*C. botulinum* is an anaerobic Gram-positive bacillus that produces heat resistant spores that can survive boiling. Under conditions of an anaerobic environment, low acidity (pH greater than 4.6), and low temperature the organism can germinate, grow, and produce a neurotoxin that itself is readily inactivated by heat (greater than 85°C for 5 minutes) [2].

Seven distinct antigenic neurotoxins (A through G) may be produced by *C. botulinum* but only four types—A, B, E, and F—are associated with human disease. Food-borne botulism occurs after the ingestion of preformed toxin in foods contaminated by spores. Wound botulism occurs when spores infect traumatized or contaminated skin. Infant botulism occurs in infants 3 to 26 weeks old after intestinal colonization by *C. botulinum* [3]. Botulism of undetermined etiology occurs among adults whose intestinal flora has been altered or whose gastric barrier has been compromised because of intestinal surgery, gastric achlorhydria, or antibiotic therapy [3,4].

All botulinum toxins have the same mechanism of action [3]. The toxin is carried via the bloodstream to the neuromuscular junction where it binds irreversibly and thereby produces paralysis. However, it does not affect the central nervous system or the adrenergic nervous system [2]. The toxin is a zinc-containing endopeptidase that cleaves to specific sites on three proteins (VAMP, SNAP25, and syntaxin), interfering with the release of acetylcholine [5]. Paralysis correlates with the amount of toxin ingested and the length of the affected nerve with short cranial nerves affected first and long lower extremity nerves last.
EPIDEMIOLOGY

There have been approximately 20 cases of food-borne botulism annually in the United States, with the majority of cases caused by toxin type A (50%), followed by toxin type E (37%), and then toxin type B (10%) [2]. Food-borne botulism has traditionally been associated with home-processed foods. However, a number of cases have been associated with commercially prepared foods that have inadvertently been processed in a manner that allowed the production of the toxin. Recently, small outbreaks have been reported in prisons associated with the production of Pruno, an alcoholic beverage made from foodstuffs that in the reported outbreaks included potatoes [6].

Wound botulism has primarily been seen in intravenous drug users who present with cranial nerve palsies in the setting of abscesses from heroin use [7]. California has accounted for over 75% of US cases, with an epidemic noted in individuals injecting black tar heroin [8].

Iatrogenic botulism has rarely developed after botulinum toxin (Botox) has been injected for cosmetic or neurologic purposes [9,10]. Although, the normal concentration of botulinum toxin A in the therapeutic preparation allows for a large margin of safety with minimal treatment side effects, therapeutic doses have been reported to cause generalized muscle weakness with widespread electromyogram (EMG) abnormalities typical of botulism [11]. In addition, four individuals have contracted botulism after receiving unlicensed preparations of botulinum toxin for cosmetic purposes [12].

Botulism toxin is the most poisonous substance known to man with 1 g of toxin able to potentially kill one million people [10]. Given its ease of production and transport, it is a major bioterrorism threat and is classified as a category A biological agent. Botulism toxin was used as a bioweapon in the 1930s by the Japanese military who fed cultures of *C. botulinum* to prisoners during that country’s occupation of Manchuria [13]. Aerosols derived from botulism toxin were also dispersed in Japan on at least three different occasions by a Japanese cult, although for unclear reasons these terrorist attempts failed [13] (see Chapter 130).
CLINICAL MANIFESTATIONS

Clinical manifestations of all forms of botulism are similar. Cardinal features include (a) cranial nerve palsies, (b) descending paralysis, (c) symmetry in symptoms, (d) absence of fever, (e) clear sensorium, and (f) lack of sensory findings [2]. Food-borne botulism may be preceded by gastrointestinal symptoms such as cramps, nausea, vomiting, and diarrhea [3,14]. Infant botulism is usually characterized by a history of constipation and feeding difficulties [3,14].

Patients may complain of dry mouth secondary to parasympathetic blockade as well as neurologic symptoms such as dysphagia, dysphonia, diplopia, and dysarthria related to palsies of the bulbar musculature. Symptoms then progress to involve lower extremity weakness and loss of the protective gag reflex requiring respiratory support. Physical examination is significant for a lack of fever except in cases of wound botulism with secondarily infected wounds. Sensory findings are absent except for periorbital paresthesias secondary to hyperventilation. Deep tendon reflexes, although present initially, usually disappear. Ocular findings are common and include dilated, poorly reactive, or fixed pupils, ptosis, nystagmus, and sixth cranial nerve dysfunction. A clear sensorium is usually present because the toxin does not usually penetrate the central nervous system [3,14].

The incubation period of food-borne botulism is usually 12 to 36 hours after toxin ingestion but may be as short as 2 hours [3,14]. Severity of disease depends on the amount of toxin that is absorbed into the system. Mortality has improved with the advances in critical care, and eventual recovery is seen in 95% of cases in the United States [9]. The recovery period may be protracted and is dependent on the reinnervation of paralyzed muscle fibers [13,15].
DIAGNOSIS

Successful diagnosis of botulism requires a high index of suspicion for the disease given that the symptoms and laboratory values are often nonspecific. If there is a suspected case of botulism, the local state health department should be notified [16]. The Centers for Disease Control and Prevention (CDC) can also be contacted through its 24-hour botulism consultation service for additional information at 770-488-7100. Prior to the administration of antitoxin, a serum sample (10 to 15 mL) should be collected and refrigerated. Anaerobic cultures and toxin assays of stool, serum, and gastric aspirates, suspected foodstuff, or wounds should be collected. Early cases are more likely to be diagnosed by toxin detection, while later cases are confirmed by culture [17]. The only acceptable method for the detection of the botulism neurotoxin is the mouse bioassay in which a patient’s serum or supernatant from a culture of the patient specimens suspected to contain toxin is administered to pairs of mice with and without toxin, serving to confirm the diagnosis and define the circulating toxin. However, a study of clinical wound botulism revealed the sensitivity of the assay to be only 68% [18].
DIFFERENTIAL DIAGNOSIS

Diseases mistaken for botulism include brainstem infarction, polyradiculopathies such as the Guillain-Barre syndrome or its Miller Fisher variant, myasthenia gravis (MG), brainstem infarction, tick paralysis, polio, meningitis, or encephalitis and poisonings such as carbon monoxide, shellfish, or organophosphate poisoning [2,9]. An improvement of strength after the edrophonium test is suggestive of MG but has also been reported in botulism [19]. The Guillain-Barre syndrome is characterized by an ascending paralysis and usually, but not always, an elevated cerebrospinal fluid protein level initially. Electrophysiologic studies may be helpful in distinguishing between causes of flaccid paralysis such as myasthenia gravis, the Guillain-Barre syndrome, and the Lambert Eaton syndrome. Normal nerve conduction velocity, absence of sensory deficits, and a small increment of motor response seen on repetitive nerve stimulation at 20 Hz (as compared with the 4 Hz in MG) are characteristic of botulism. Tick paralysis is diagnosed by the presence of an embedded Dermacentor tick. Altered mental status is usually seen in encephalitis, organophosphate, and carbon monoxide poisonings rather than botulism. Shellfish poisoning presents with tremors and paresthesias that are usually absent in botulism [2].
TREATMENT

The mortality rate from botulism has decreased dramatically since the first decades of the 20th century to its current rate of 3% to 5% with the advent of intensive care units [20], and all patients suspected of botulism should initially be monitored in an intensive care setting.

Therapy consists of toxin removal, supportive care, including nutritional support, and passive immunization with equine antitoxin [3]. Patients should be assessed and monitored for the adequacy of cough, the control of oropharyngeal secretions, and ventilation. Please refer to the chapter on extrapulmonary causes of respiratory failure for guidelines on how to monitor for the adequacy of ventilation and when to consider endotracheal intubation (Chapter 165); and to the chapter on invasive mechanical ventilation for guidelines on how to ventilate patients with respiratory failure due to neuromuscular diseases.

For adults and older children, passive immunization with equine antitoxin should be administered as soon as botulism is diagnosed. Antitoxin will only neutralize toxin molecules that have not bound to nerve endings. Timely administration minimizes subsequent nerve damage and severity of disease but will not reverse existing paralytic damage [21]. The preferred antitoxin is the heptavalent equine antitoxin available through the CDC [22]. Clinicians should contact their local state health departments or the CDC (770-488-7100). Additional assistance can be obtained through the US Army, USAMRIID (888-872-7443). Patients should be skin tested prior to antitoxin administration and desensitized using the protocol enclosed with the antitoxin if there is any evidence of a wheal and flare reaction. A single case of intestinal botulism is documented as being refractory to toxin administration. This is explained by the shorter half-life of the heptavalent preparation and ongoing toxin production from the intestinal bacterium [23]. This is not an issue with the more common food-borne cases in which continued toxin production does not occur.

Equine antitoxin is not recommended for treatment of infants suspected of botulism because of the potential serious side effects of serum sickness and anaphylaxis. However, a 2006 study found that the administration of human botulism immune globulin intravenous within 72 hours of hospitalization for suspected infant botulism decreased illness severity, shortened hospital stays, and reduced costs [24]. This preparation, human botulism immune globulin (Baby-BIG), is now FDA agent approved and available through the California Department of Public Health.

Patients with wound botulism also require aggressive wound
debridement regardless of how well the wound appears as toxin is produced until the infection is eliminated. Antitoxin should be administered prior to surgery to neutralize toxin released by the procedure. Penicillin therapy, 10 to 20 million units per day, is appropriate [5,8]. Aminoglycosides and clindamycin should be avoided because of the potential for neuromuscular blockade [25,26].

Because botulinum toxin is not absorbed through intact skin, standard precautions should be undertaken when caring for patients suspected of botulism. There have been no cases of human-to-human transmission described [9].

A number of potential vaccine candidates remain investigational with no phase 3 studies reported to date.

Advances in botulism, based on randomized controlled trials, are summarized in Table 86.1.

REFERENCES

Tetanus, caused by the neurotoxin tetanospasmin, is produced by the anaerobic spore-forming gram-positive bacterium *Clostridium tetani*. Clinically, tetanus presents with skeletal muscle rigidity and spasms that classically involve the muscles of the face (lockjaw). It is a relatively rare clinical entity in developed countries because of the broad use of tetanus toxoid (TT) immunization. However, tetanus still occurs frequently in the third world, and in individuals who have never been or have been inadequately vaccinated in the setting of a wound infection or another portal of entry. Diagnosis is based on clinical suspicion and the exclusion of other entities because of a lack of timely confirmatory testing. Treatment relies mainly on respiratory support and symptomatic management of the muscular rigidity and spasms and the autonomic manifestations of the disease.

**PATHOGENESIS**

*Clostridium tetani* is an obligate anaerobic spore-forming bacillus which is ubiquitous in the environment. Mature organisms develop spores that are widely distributed in soil and dust as well as in the intestines and feces of animals. The vegetative form of *C. tetani* produces two types of zinc metalloproteinase toxins, tetanospasmin and tetanolysin, with tetanospasmin playing a more prominent role in pathogenesis. The *C. tetani* neurotoxin is of a single antigenic type and specifically targets the central nervous system (CNS), including the peripheral motor end plates, spinal cord, brain, and the sympathetic nervous system [1,2]. Although this toxin can exert an excitatory effect, it acts primarily by blocking the release of neurotransmitters such as glycine and gamma-amino butyric acid, which normally act to inhibit the transmission of motor nerve impulses. Specifically, the toxin degrades synaptobrevin, a protein required for contact of inhibitory neurotransmitter vesicles with their
release site on the presynaptic membrane [3].

Antitoxin is of therapeutic value only for protecting neurons that have not already bound the toxin. As the effect of the toxin on a synapse does not appear reversible, recovery from tetanus depends on the generation of new nerve terminals and new synapse formation.
Epidemiology

Tetanus is endemic in the developing world with neonatal tetanus accounting for the majority (>50%) of deaths due to tetanus [4]. Tetanus is a rare disease in the developed world with morbidity and mortality in the United States declining steadily, due to the availability of tetanus vaccines, improved wound management and the use of tetanus immunoglobulin for postexposure prophylaxis [4]. According to 2001 to 2008 surveillance data, a history of incomplete TT immunization and inadequate wound prophylaxis remain the most important factors associated with tetanus [5]. Age ≥ 65 years old remained the highest risk factor for fatal tetanus with a case fatality rate of 31.3%. [5]. Sporadic cases of tetanus have been reported in those with a tetanus antibody level adequate for protective immunity [6].
CLINICAL MANIFESTATIONS

Tetanus usually occurs in the setting of either a penetrating wound, foreign body or necrotic or infected tissue in which anaerobic bacterial growth is facilitated [7]. However, in up to 30% of cases, no acute injury is reported [8]. The incubation period for tetanus varies from 3 to 21 days, with the length of the incubation period dependent on how far the injury site is from the CNS [9]. The first nerves affected are the shortest, accounting for the early symptoms of facial distortion and neck stiffness. The shorter the incubation period, the worse the prognosis [10].

Clinical tetanus can present in three forms—local, cephalic, and generalized—with 80% of cases being generalized. Local tetanus presents as a focal region of muscle contraction at a site of spore inoculation [1]. Symptoms may persist but usually resolve spontaneously. Cephalic tetanus develops after a traumatic head injury, but has been reported after otitis media when C. tetanus was present in the middle ear [11]. Typically, there is involvement of the cranial nerves, especially cranial nerve VII in the facial area.

Generalized tetanus typically presents with involvement of facial musculature, starting with masseter rigidity (lockjaw or trismus) and risus sardonicus (orbicularis oris), and then progresses in a descending fashion with difficulty swallowing and abdominal rigidity [1]. Spasms, which are often triggered by sensory stimuli, are common and may resemble seizures with flexion of the arms and the extension of legs (opisthotonus). Loss of consciousness is uncommon and severe pain usually accompanies the spasms. Laryngospasm and respiratory compromise may result from vocal cord or diaphragmatic spasms and upper airway obstruction. Fractures of the spine or the long bones, dislocations, and rhabdomyolysis may occur as a result of spasms. The course of this illness occurs over 2 weeks, reflecting the time it takes for intraaxonial toxin to travel to the CNS. Spasms occur within the first 2 weeks of illness followed by autonomic disturbances such as extremes in blood pressure and cardiac arrhythmias including sinus tachycardia and cardiac arrest [12,13]. Individuals with tetanus are at high risk of nosocomial pneumonia with an incidence of approximately 35%. Autonomic dysfunction is an independent risk factor for pneumonia in patients with tetanus [14].

Neonatal tetanus, more often seen in developing countries, is a form of generalized tetanus that commonly arises when an unhealed umbilical stump becomes infected after an incision with an unsterile instrument and if the mother had not been adequately immunized [1,9].
DIAGNOSIS

No laboratory test is available that provides a definitive diagnosis of tetanus. Diagnosis is clinical and primarily based on the presence of trismus, dysphagia, muscular rigidity, and spasm. Unusual presentations such as meningitis should be considered in the setting of risk factors such as a history of a contaminated wound [15].

Few other conditions present with muscular rigidity and sympathetic hyperreactivity except for strychnine poisoning. Strychnine blocks the inhibitory glycine receptor in the spinal cord and the brain. Unlike tetanus, however, the sudden contraction of all striated muscles is usually followed by complete relaxation of these muscles. Additional conditions that can mimic the spasms seen in tetanus include hypocalcemia and reactions to certain medications including neuroleptic drugs and central dopamine antagonists. Odontogenic infections can produce trismus but not the other manifestations of tetanus [1].
TREATMENT

The mortality rate in tetanus varies from 6% in mild to moderate tetanus up to 60% in the severest of cases [1,16]. Autonomic nervous system dysfunction has been shown to predict a poor outcome in mild to moderate cases of tetanus [17]. Illness is less severe among patients who have received a complete immunization series of TT compared with those who were never or inadequately vaccinated [18].

Individuals suspected of generalized tetanus should be observed in an intensive care setting with minimal stimuli. Initial management consists of airway stabilization and general intensive care support including mechanical ventilation, nutritional support, and deep venous thrombosis prophylaxis. Benzodiazepines such as midazolam, lorazepam, and diazepam have been the mainstay of treatment [1]. This class of agents acts as γ-aminobutyric acid (GABA) agonists, thus indirectly opposing the effects of the toxin by competing for receptor sites [2]. Doses are initially titrated to produce sedation and limit reflex spasms. Propofol (alone or in combination with benzodiazepines) and intrathecal baclofen are alternative options that have been used [19,20]. Intravenous diazepam and lorazepam contain propylene glycol, which may increase the risk of lactic acidosis at the recommended doses of treatment [21]. If the muscle spasms cannot be controlled with these agents, a neuromuscular paralytic agent such as vecuronium can be added [1]. Once the symptoms have resolved, benzodiazepines should be tapered to prevent withdrawal.

Botulinum toxin acts mainly on lower motor neurons by inhibiting acetylcholine release and muscle activity. Direct injection of botulinum toxin into the muscle has been successfully used in a small number of patients to reduce tetanus induced rigidity and spasm [22].

If a portal of entry can be identified, the wound should be debrided and an antibiotic active against anaerobic organisms should be administered with metronidazole for 7 to 10 days now considered to be the first line of therapy. Treatment courses of 7 to 10 days using regimens of penicillin, either as a single-dose intramuscular benzathine dose or intravenous benzyl penicillin are alternative regimens [1,23]. Alternative regimens such as doxycycline, clindamycin, vancomycin, and chloramphenicol are likely to be effective given susceptibility data against C. tetani [24]. Passive immunization with human tetanus immunoglobulin (at a dose of 500 units) may shorten the course and severity of tetanus by neutralizing toxin that has not reached the CNS [25]. In a randomized clinical trial, patients treated with intrathecal rather than intramuscular administration of human antitetanus immunoglobulin showed better clinical progression including fewer respiratory complications and
significantly shorter duration of spasms [26], though methodical issues with the study have been raised [7].

Autonomic dysfunction is usually related to excessive catecholamine release and can be treated by a combined $\alpha$- and $\beta$-blocker such as labetalol. Beta-blockade alone may result in severe hypertension due to an unopposed $\alpha$ effect [27]. Magnesium sulfate has been studied in a randomized controlled trial and found to reduce the requirements of other drugs to control spasms and cardiac instability [28].

As the amount of toxin causing disease may be too small to induce a consistent immunological response, active immunization with three doses of TT should be given at diagnosis, at 4 to 6 weeks and 1 year later to prevent future attacks [1,9]. TT should be given at a site different than tetanus immunoglobulin [7].

Over the past 30 years, there have only been nine randomized clinical trials that have addressed therapeutic interventions [29]. Advances in tetanus, based on randomized controlled trials are summarized in Table 87.1.

HEMATOLOGIC AND ONCOLOGIC PROBLEMS IN THE INTENSIVE CARE UNIT
PATRICK F. FOGARTY
Disorders of hemostasis are common in critically ill patients. This chapter will review hemostasis, pathophysiology of commonly encountered congenital and acquired bleeding disorders along with their associated symptoms, laboratory findings, and management.

**REVIEW OF NORMAL HEMOSTASIS**

Hemostasis can be broken into a series of steps occurring in overlapping sequence. Primary hemostasis refers to the interactions between the platelet and the injured vessel wall, culminating in the formation of a platelet plug. The humoral phase of clotting, or secondary hemostasis, encompasses a series of enzymatic reactions, resulting in a hemostatic fibrin plug. Finally, fibrinolysis and wound repair occur. Each of these steps is carefully regulated, and perturbations can predispose to either hemorrhage or thrombosis. Depending on the nature of the defect, the hemorrhagic or thrombotic tendency can be either profound or subtle.

Primary hemostasis begins at the site of vascular injury, with platelets adhering to the subendothelium, utilizing interactions between molecules such as collagen and von Willebrand factor (vWF) in the vessel wall with glycoprotein (GP) receptors on the platelet surface. Upon exposure to agonists present at a wounded vessel, signal transduction leads to platelet activation. Via a process known as inside-out signaling, the platelet membrane integrin $\alpha_{2b}\beta_3$ (also known as GP IIbIIIa) undergoes a conformational change to be able to bind fibrinogen, which cross-links adjacent platelets, leading to platelet aggregation. Secretion of granular contents is also triggered by outside signals, potentiating further platelet activation (Fig. 88.1). Lastly, the surface of the platelet changes to serve as an adequate scaffold for the series of biochemical reactions resulting in
thrombin generation.

**FIGURE 88.1** Primary hemostasis. (1) Exposure of subendothelium at sites of vascular disruption results in platelet adhesion via GPIb and GP VI with exposed von Willebrand factor (vWF) and collagen, respectively. Following platelet adhesion, TxA$_2$ is produced and released, which promotes vasoconstriction and platelet aggregation. (2) Platelet adhesion also results in fusion of cytoplasmic granules to the plasma membrane. Release of alpha and dense granules activates nearby platelets. (3) Platelet activation results in exposure of GPIIb/IIIa on the platelet surface allowing fibrinogen to cross bridge platelets resulting in a platelet plug.

Following platelet activation, a series of enzymatic reactions take place on phospholipid surfaces, culminating in the formation of a stable fibrin clot. Several models have attempted to make sense of these reactions. The cascade model was developed by two groups nearly simultaneously in 1964 and explained the extrinsic, intrinsic, and common pathways leading to fibrin formation (Fig. 88.2). Although the cascade model accounts for the physiologic reactions underlying the prothrombin time (PT) and the activated partial thromboplastin time (aPTT), it fails to explain completely the bleeding diathesis seen in individuals deficient in factors XI, IX, and VIII, as well as the lack of bleeding in those deficient only in contact factors. A cell-based model of hemostasis has been developed to address these deficiencies [1]. In this model, upon vascular injury, the membrane of a tissue factor (TF)-bearing cell such as an activated monocyte or fibroblast serves as a platform for generation of a small amount of thrombin and FIXa, which then serves to activate platelets and cleave FVIII from vWF. Newly formed FVIIIa participates in
the tenase complex on the surface of activated platelets to form FXa that interacts with the FVa generated on the platelet surface to form the prothrombinase complex. This complex generates a large burst of thrombin which is sufficient to cleave fibrinogen, activate FXIII, and activate the thrombin-activatable fibrinolysis inhibitor, thus allowing for formation of a stable fibrin clot (Fig. 88.2).

Fibrinolysis leads to clot dissolution once wound healing has occurred, in order to restore normal blood flow. Plasminogen is activated to plasmin by the action of either tissue plasminogen activator (t-PA) or
urokinase plasminogen activator. Plasmin degrades fibrin and fibrinogen and can thus dissolve both formed clot as well as its soluble precursor. Plasmin is inhibited by a number of inhibitors, of which $\alpha_2$-plasmin inhibitor is the most significant. Plasminogen activation is also inhibited by a number of molecules; chief among them is plasminogen activator inhibitor-1. Lastly, cellular receptors act to localize and potentiate or clear plasmin and plasminogen activators (see Chapter 93 for further discussion).
Physicians in the intensive care unit (ICU) often encounter bleeding patients and it can be difficult to identify which of these patients require further evaluation. Patients who experience bleeding that is excessive, spontaneous, or delayed following surgery or tissue injury require further investigation, which must begin with a thorough clinical history. A bleeding history should assess a patient’s exposure and response to all hemostatic challenges in the past such as trauma, surgery, and childbirth. Characterization of menses in females also may be revealing. Several bleeding assessment tools have been developed and are useful in the evaluation for an underlying coagulopathy, particularly von Willebrand disease (vWD) [2]. This history should also identify coexisting medical conditions such as liver, kidney, or thyroid disorders. A careful medication history is also important, including use of all over-the-counter medications which may contain aspirin, as well as any herbal preparations. Also of importance is an evaluation for a family history of abnormal bleeding. An inherited or congenital bleeding disorder is suggested by abnormal bleeding with onset shortly after birth and persistence throughout life. It is further supported by a family history with a consistent genetic pattern. However, it is important to note that a negative family history does not exclude a congenital bleeding disorder. For instance, approximately one-third of all cases of hemophilia A arise from spontaneous mutations. Many of the rare coagulation disorders, including deficiency of factors II, V, VII, X, as well as vWD type 2 N, among others, are inherited in an autosomal recessive fashion, and the parents of the patient may be entirely asymptomatic.

A bleeding history should also ascertain past sites/mechanisms of bleeding. Surgical bleeding in patients with an underlying hemorrhagic condition is typically described as “diffuse oozing,” without the readily identifiable bleeding source seen with a surgical mishap such as a severed vessel. Patients with platelet disorders typically manifest mucocutaneous bleeding such as gingival bleeding and epistaxis as well as menorrhagia, petechiae, and ecchymoses. Platelet defects impact primary hemostasis and therefore the bleeding in these disorders is often immediate following surgery or trauma, whereas delayed bleeding is more classically associated with coagulation disorders. Patients with coagulation defects typically present with hemorrhages into soft tissues such as muscles and joints.
LABORATORY ASSAYS OF PRIMARY AND SECONDARY HEMOSTASIS

Although the history and physical examination can increase suspicion for the presence of a bleeding disorder, laboratory confirmation is required for precise diagnosis and treatment. Laboratory evaluation is particularly crucial in individuals who are suspected of having a bleeding disorder but in whom prior bleeding is absent, such as those with mild congenital bleeding disorders who never previously underwent a sufficient hemostatic challenge, or those with acquired hemorrhagic disorders.

Initial Evaluation of Primary Hemostasis—Platelet Function

An assessment of a patient’s platelet count is fundamental in evaluating primary hemostasis. This is typically part of a complete blood count. Reduced platelet counts, or thrombocytopenia, may be seen in a large number of acquired and congenital conditions. Evaluation and management of thrombocytopenia is further discussed in Chapter 91.

An evaluation of the peripheral smear is also cardinal in any evaluation of a bleeding patient. It allows one to assess platelet size and morphology, presence of platelet clumping (pseudothrombocytopenia), leukocyte inclusions, and red cell fragments, among other aberrancies, which may further direct workup and treatment.

Traditionally, platelet function was evaluated by bleeding time (BT). However, many institutions have discontinued using this test given the difficulty in standardization. Furthermore, the BT has been shown to be an inadequate predictor of bleeding, particularly in preoperative risk assessment [3]. More recently, automated tests have been developed to assess platelet function. The most widely used is the platelet function analyzer (PFA-100). This assay measures the time required (closure time) for flowing whole, citrated blood to occlude an aperture in a membrane impregnated with a combination of either collagen and epinephrine or collagen and adenosine diphosphate (ADP). Closure time is affected by platelet count, hematocrit, platelet function, and vWF [4]. The PFA-100 appears to assess platelet function with greater sensitivity and
reproducibility than the BT; however, it may not have sufficient sensitivity or specificity to be used as a screening tool for platelet disorders [5].

**Evaluation of Secondary Hemostasis—Coagulation**

The PT and the aPTT are assays performed on citrated plasma, which require enzymatic generation of thrombin on a phospholipid surface. Prolongation of the PT and the aPTT can be seen in individuals with either deficiencies of, or inhibitors to, humoral clotting factors, though not all patients with prolongations of these assays will have bleeding diatheses (Table 88.1).

The PT measures the time needed for formation of an insoluble fibrin clot once citrated plasma has been recalcified and thromboplastin has been added, indicating activity of factors VII, V, X, and II, and fibrinogen. It is commonly used to monitor anticoagulation with vitamin K antagonists such as warfarin. As thromboplastin from various sources and different lots can affect the rates of clotting reactions, the International Normalized Ratio (INR) measurement was developed to avoid some of this variability in PT measurement. Each batch of thromboplastin reagent has assigned to it a numerical International Sensitivity Index (ISI) value, which is used in the formula:

\[
\text{INR} = \left( \frac{\text{PT}_{\text{patient}}}{\text{PT}_{\text{normal}}} \right)^{\text{ISI}}
\]

The INR is less predictive of bleeding in patients with liver disease, and can be inaccurate in patients with lupus anticoagulants that are strong enough to affect the PT.

The aPTT tests the activity of factors XII, XI, IX, VIII, X, V, and II, and fibrinogen, high-molecular-weight (HMW) kininogen, and plasma prekallikrein [6]. Citrated plasma is recalcified, and phospholipids (to provide a scaffold for the clotting reactions) and an activator of the intrinsic system such as kaolin, celite, or silica are added. The reagents used show variable sensitivities to inhibitors such as lupus anticoagulants and heparin, and to deficiencies (if any) in involved clotting factors, and normal ranges will vary from laboratory to laboratory. aPTT values that are vastly different from one laboratory to another should prompt suspicion of a lupus anticoagulant.

**The Thrombin Clotting Time and Reptilase Time**

The thrombin clotting time or thrombin time (TT) measures the time needed for clot formation once thrombin is added to citrated plasma. Thrombin enzymatically cleaves fibrinopeptides A and B from the α and β-chains of fibrinogen, allowing for polymerization into fibrin. The TT is prolonged in the presence of any thrombin inhibitor such as heparin, lepirudin, or argatroban; by low levels of fibrinogen or structurally abnormal fibrinogen (dysfibrinogens); and by elevated levels of fibrinogen or fibrin degradation products, which can serve as nonspecific inhibitors of the reaction. Patients with paraproteins can have a prolonged TT because of the inhibitory effect of the paraprotein on fibrin polymerization.
Reptilase is snake venom from *Bothrops atrox* which also enzymatically cleaves fibrinogen. Reptilase cleaves only fibrinopeptide A from the α-chain of fibrinogen, but fibrin polymerization still occurs. Reptilase time (RT) is not affected by heparin but may be more sensitive than the TT to the presence of a dysfibrinogenemia.

**Mixing Studies**

Mixing studies are used to evaluate prolongations of the aPTT (less commonly the PT or the TT) and are useful in making the distinction between an inhibitor and a clotting factor deficiency. The patient’s plasma is mixed 1:1 with normal control plasma, and the assay is repeated (with or without prolonged incubation at 37°C). Correction of the clotting test signifies factor deficiency, as the normal plasma will supply the deficient factor. Incomplete correction of the clotting test after mixing suggests the presence of an inhibitor, as an inhibitor will prolong clotting in normal plasma. Incomplete correction can sometimes be seen with nonspecific inhibitors such as lupus anticoagulants, elevated fibrin split products, or a paraprotein. Less commonly, deficiencies of multiple clotting factors can lead to incomplete correction of the mixing study, as the mixing study was designed to correct deficiency of a single factor.

Tests of specific factor activity levels as well as evaluation for vWD will be discussed in the following sections.
CONGENITAL DISORDERS OF HEMOSTASIS

Due to a requirement for specialized management, all cases of suspected or proven congenital hemostatic defects require consultation with a hematologist upon admission to the critical care setting.

von Willebrand Disease

It has been estimated that lower-than-reference levels of vWF occur in 1% of the population worldwide and therefore vWD is the most common congenital bleeding disorder. However, only a fraction of the aforementioned individuals are symptomatic (approximately 5% of those with low levels) \[7\]. vWD is inherited in an autosomal manner with the more common type I disease being autosomal dominant.

vWD constitutes a quantitative or qualitative deficiency in vWF, and is divided into three subtypes according to the pathophysiology. Types 1 and 3 are the result of a partial (type 1) or virtually a complete (type 3) quantitative deficiency of vWF, whereas type 2 is a qualitative defect in vWF. Type 1 vWD represents the most common subtype accounting for approximately 70% of patients, whereas type 2 accounts for 15% to 20% and type 3 for only 2% to 5% of vWD patients \[6\].

Because bleeding symptoms in persons with vWD may be absent or overlooked until a major hemorrhage due to surgery or trauma has occurred, the diagnosis should be considered in an ICU patient with otherwise unexplained excessive bleeding, particularly if there is a significant family history including an autosomal pattern of inheritance. The most common historical bleeding symptoms include epistaxis, increased bleeding after dental extractions, and menorrhagia. A validated bleeding assessment tool has been developed to screen outpatients who may benefit from formal vWD laboratory testing, but its usefulness in the critical care setting has not been established.

A formal diagnosis of vWD should be based on three components: (a) a history of excessive bleeding, either spontaneous, mucocutaneous and/or postsurgical, (b) a positive family history for excessive bleeding, and (c) confirmatory laboratory testing. Diagnostic tests for vWD, reviewed elsewhere \[6\], should be performed in a specialized laboratory and are summarized in Table 88.2.

The symbols and values represent prototypical cases. In practice, laboratory studies in certain patients may deviate slightly from these expectations.

The goals of treatment in vWD are to correct the quantitative or qualitative deficiencies in vWF, platelets, and FVIII. Treatment options include desmopressin (DDAVP), vWF-containing concentrates, and/or antifibrinolytics. See Tables 88.3 and 88.4 for general treatment.

\(^a\) Loading dose is in vWF:RCo IU/dL.

In normal volunteers, DDAVP increases plasma levels of FVIII, vWF, and t-PA [8]. It may be given by the intravenous, subcutaneous, or intranasal route [9]. When given intravenously, the FVIII and vWF levels are usually increased three- to fivefold above basal levels within 30 minutes. vWD patients should undergo a DDAVP trial to gauge their individual response as there is considerable interindividually variability.
Dosing of DDAVP for vWD is generally recommended at 0.3 μg per kg (IV or SQ), or 300 μg intranasally, which can be repeated at intervals of 12 to 24 hours. Tachyphylaxis (due to depletion of FVIII/vWF from repeated endothelial exocytosis into plasma) following repeated dosing is expected; DDAVP given as a second dose is 30% less effective than the first dose [10]. For this reason, and because of the risk of hyponatremia (which can lead to seizures), serial dosing should be limited to two to three doses in a 72-hour period with concurrent free water restriction and monitoring of serum sodium levels. DDAVP is most effective in type 1 vWD. It is relatively contraindicated in type 2B vWD because of the transient induction of thrombocytopenia. Patients with type 3 vWD are usually unresponsive to DDAVP. Certain hemophilia treatment centers caution against the use of DDAVP in patients with coronary artery disease, as this agent may also activate platelets.

Antifibrinolytic agents (epsilon aminocaproic acid and tranexamic acid) can be used alone or as adjunctive treatment in vWD patients with mucosal bleeding. These drugs inhibit fibrinolysis by inhibiting plasminogen activation, thereby promoting clot stability. They are contraindicated in the setting of gross hematuria as resultant ureteral obstruction by insoluble clot has been described. Given a concern for thrombosis, antifibrinolytics should be avoided in patients with prothrombotic conditions, disseminated intravascular coagulation (DIC), or when receiving prothrombin complex concentrates (PCCs).

vWF factor-containing FVIII concentrates are appropriate for patients with severe vWD or in situations when other therapies (including DDAVP) are ineffective and are preferred to cryoprecipitate, which contains vWF, but has not undergone viral inactivation. When used in the treatment of vWD, they are dosed in ristocetin cofactor (RCoF) units, as opposed to FVIII units (Table 88.4). Limited data suggest a role for rFVIIa in patients with type 3 vWD who have developed alloantibodies to vWF.

The National Heart Lung and Blood Institute has published guidelines for the diagnosis, evaluation, and management of vWD [6].

Hemophilia

The hemophilies are congenital bleeding disorders characterized by X-linked inheritance and result in a deficiency of FVIII (hemophilia A) or FIX (hemophilia B). In the United States, they have a combined incidence of 1 in 5,000 male births. Hemophilia A is more common than
hemophilia B and accounts for approximately 80% of cases. Because hemophilia is an X-linked disorder, all daughters of affected males are obligate carriers and all sons are healthy. Females may rarely manifest bleeding symptoms if they (a) are the homozygous offspring from a carrier mother and affected father, (b) have a high degree of lyonization, or (c) are a carrier with concomitant Turner’s syndrome (XO).

The clinical phenotype of hemophilia patients depends on the residual level of circulating procoagulant protein (FVIII or FIX). It is possible to differentiate three degrees of clinical severity: (a) mild hemophilia (5% to 50% factor activity) in which bleeding is prolonged but typically only occurs following trauma or surgery, (b) moderate hemophilia (1% to 5% factor activity) in which prolonged bleeding follows minor trauma, and (c) severe hemophilia (<1% factor activity) where patients experience spontaneous hemorrhage into joints (hemarthrosis) and muscles.

In severe and moderate hemophilia, the PT is normal and the aPTT is prolonged. However, the PTT may be normal in patients with mild hemophilia whose residual factor activity is >20%. If the aPTT is prolonged, it should correct with a mixing study, as hemophilia is a factor deficiency syndrome. Specific factor assays should be performed to confirm a diagnosis of hemophilia A or B.

The management of most cases of hemophilia, thanks to the availability of replacement clotting factor concentrates, occurs in the outpatient setting, but individuals who previously have escaped diagnosis (mild or moderate hemophilia) or who have sustained major trauma or complications from a bleeding episode (compartment syndrome) may present to critical care. If not previously diagnosed, hemophilia should be suspected in male patients who have a personal history of bleeding into joints or muscles, a history of excessive bleeding upon surgical challenge, and/or a positive sex-linked family history of bleeding.

Hemarthrosis, a hallmark of hemophilia, accounts for approximately 85% of all bleeding events in severe hemophilia and most commonly involves the ankles, knees, and elbows. Intramuscular hematomas in persons with hemophilia may expand to the point where blood flow is compromised to surrounding neurovascular structures resulting in tissue gangrene and compartment syndrome; the condition requires surgery and aggressive clotting factor replacement therapy [11] (Table 88.5). Gastrointestinal bleeding is uncommon in hemophilia. However, patients with an underlying structural lesion may present with hematemesis, hematochezia, or melena. Hemophilia patients who present with evidence for gastrointestinal bleeding should have a complete endoscopic evaluation to assess for and treat any underlying lesion. Approximately 90% of persons with severe hemophilia will develop hematuria during their life, although the condition is typically painless, benign, and unassociated with a structural lesion. As discussed earlier, antifibrinolytic
agents are contraindicated in patients with genitourinary bleeding.

¹Minimum recommended goal factor activity levels. EACA, epsilon aminocaproic acid.

Hemorrhage into head and neck structures is a medical emergency in persons with hemophilia. Retropharyngeal hematoma, which may occur spontaneously or following dental or surgical procedures, may present with inability to control saliva, neck swelling, and pain. If untreated, it may result in airway compromise and in some cases may require tracheostomy. Hemorrhage into the central nervous system is a severe and potentially fatal (albeit rare) complication of hemophilia. Intracranial hemorrhage (ICH) may occur spontaneously in severe hemophilia or as the result of trauma. Prompt recognition of ICH is paramount and factor replacement therapy should be given immediately while the diagnostic workup is underway (Table 88.5).

The approach to treating major bleeding episodes in hemophilia A and B is similar. The clinical scenario dictates the target factor activity level (Table 88.5). For example, an ICH requires a target activity level of 100% initially, whereas levels of 30% to 40% may be sufficient for minor bleeds such as uncomplicated hemarthrosis. Prior to completion of the diagnostic (radiologic or otherwise) workup, clotting factor concentrate should be administered immediately to a person with hemophilia and a suspected life- or limb-threatening bleed. Plasma-derived and
Recombinant factor concentrates contain much higher concentrations of the desired factor compared to fresh frozen plasma (FFP) or cryoprecipitate. If possible, avoidance of FFP or cryoprecipitate is advised to avoid volume overload, transfusion-related lung injury (TRALI), and potential transmission of infectious agents (see Chapter 89).

DDAVP may be used instead of factor concentrate in selected patients with mild hemophilia A who have minor bleeding or a requirement for an enhanced FVIII activity level prior to a short-lived bleeding challenge. Any mild hemophilia A patient should undergo a DDAVP trial to gauge his individual response in lieu of assuming efficacy of the agent. FVIII levels in plasma increase two- to sixfold following administration. For mild hemophilia A, the recommended dose is 0.3 μg per kg (IV or SQ) or 300 μg intranasally; as previously discussed, tachyphylaxis and hyponatremia may develop after serial dosing.

Antifibrinolytic agents are a useful adjunctive treatment in hemophilia patients with mucosal bleeding. However, hemophilic patients with hematuria, DIC, receiving a PCC, or other prothrombotic conditions should not be treated with antifibrinolytics.

One of the most significant complications of hemophilia treatment is the development of an inhibitor. Inhibitors are alloantibodies against exogenously administered clotting factor that neutralize the factor. The development of a new inhibitor is more common in hemophilia A than in hemophilia B, in severe hemophilia, and among previously untreated patients (as opposed to adults who typically have been extensively exposed to clotting factor concentrate) [12].

Inhibitors, if present at high titer, neutralize exogenous factor rendering factor concentrates ineffective. Therefore, an inhibitor should be suspected when administration of factor concentrate at a dose previously sufficient to achieve hemostasis, or improve bleeding, fails to do so. Once suspected, a Bethesda assay should be performed to document the titer of the inhibitor (reported in Bethesda units, BU). Of the two goals of treatment in patients with inhibitors, namely, to achieve adequate hemostasis and to eradicate the inhibitor, only the former is typically relevant to the critical care setting. Bleeding should be treated with bypassing agents, typically an activated prothrombin complex concentrate (aPCC) or rFVIIa [13]. If the titer is <5 BU, high doses of FVIII or FIX may be given as initial treatment in cases of life- or limb-threatening bleeding episodes. In patients with a long-standing inhibitor, however, the anamnestic response negates factor activity after 5 to 7 days, at which point bypassing agents become necessary.
RARE CONGENITAL COAGULATION DISORDERS

Less Common Coagulation Factor Deficiencies

The hemophilias and vWD represent approximately 85% of congenital bleeding disorders. The remaining disorders will be briefly discussed next.

Disorders of Fibrinogen

Congenital fibrinogen disorders result from a quantitative (afibrinogenemia) or qualitative (dysfibrinogenemia) defect in fibrinogen synthesis. Congenital afibrinogenemia has a variable bleeding phenotype with the majority of patients experiencing moderate bleeding [9]. Afflicted individuals present typically in the neonatal period with umbilical stump bleeding or bleeding following circumcision. Patients may also experience hemarthrosis, intramuscular hemorrhage, spontaneous abortion, mucosal surface bleeds, ICH, or spontaneous splenic rupture [14]. Heterozygotes are typically asymptomatic. The clinical phenotype in patients with congenital dysfibrinogenemia is variable and includes (a) asymptomatic (55%), (b) hemorrhagic (25%), (c) thrombotic (10% to 20%), or (d) a combination of both hemorrhagic and thrombotic complications (1% to 2%) [15]. Treatment of congenital fibrinogen disorders should be individualized given the clinical variability. In general, replacement therapy in the form of fibrinogen concentrates, cryoprecipitate, or (not recommended) FFP should be given to patients with a hemorrhagic presentation to achieve a goal fibrinogen level of 50 to 100 mg per dL [16].

Prothrombin (FII) Deficiency

Congenital prothrombin deficiency is characterized by a concordant decrease in prothrombin antigen and activity. Aprothrombinemia has not been reported. Patients with hypoprothrombinemia present with severe hemorrhage including ICH, mucocutaneous bleeding, hemarthrosis, spontaneous abortions, and significant postoperative bleeding. Heterozygotes are usually asymptomatic; however, they may experience increased postoperative bleeding [17]. Prothrombin deficiency is treated with factor replacement in the form of FFP or PCC to a goal prothrombin level of 30% [18].
Factor V Deficiency

FV deficiency is associated with mucocutaneous bleeding and rarely with ICH [19]. There are mild, moderate, and severe deficiency states. Patients with severe deficiency usually present with umbilical stump and mucocutaneous bleeding. Older individuals may present with postoperative bleeding or menorrhagia. FV deficiency is treated with FFP to a goal activity level of 20% to 30% [20]. Alpha granules in platelets contain FV, and platelet transfusions have been used in the treatment of FV deficiency when patients have developed neutralizing inhibitors to FV with varying success [21]. Combined deficiency of FV and FVIII should always be considered in the differential diagnosis of patients who present with FV deficiency. This is discussed next.

Combined Factor V and VIII Deficiency

Combined FV and FVIII deficiency (F5F8D) is a rare disorder where patients have detectable, but low antigen and activity levels of both factors, typically in the 5% to 15% range. Patients present with increased bleeding following trauma or surgery. Patients are treated with a combination of FFP and FVIII concentrates [22].

Factor VII Deficiency

Patients with less than 1% FVII activity manifest a severe bleeding disorder, predominantly involving the mucous membranes, muscles, joints, and following surgery or trauma, whereas those with more than 5% have relatively mild symptoms. Factor VII activity correlates poorly with bleeding severity, but in general, only modest amounts of circulating FVII are required for adequate hemostasis, and bleeding is uncommon, even with surgery, in individuals with FVII activity levels >15% to 20% [23]. In the United States, rFVIIa is used to treat FVII deficiency. Plasma-derived FVII concentrates are available in Europe to treat this disorder [24,25]. When rFVIIa and/or FVII concentrates are unavailable, 4-factor PCC or FFP may be used.

Factor X Deficiency

In congenital FX deficiency, severity of bleeding appears to correlate with residual FX activity and may be quite severe. The most common symptoms appear to be epistaxis, menorrhagia, and hemarthrosis [26]. FX deficiency is treated with PCCs.

Factor XI Deficiency
FXI deficiency, previously known as hemophilia C, is common among Ashkenazi Jews where the gene frequency is 8% to 9% [27]. The inheritance is autosomal rather than X linked as with hemophilia A and B. Severe FXI deficiency (<15% to 20% FXI activity) occurs in homozygotes or compound heterozygotes. Heterozygous individuals have a partial FXI deficiency (20% to 70% FXI activity) [27]. Bleeding is unpredictable as some severe FXI-deficient patients are asymptomatic, whereas an analysis of 50 kindreds demonstrated that 30% to 50% of heterozygotes experienced significant significant bleeding [28].

Treatment for FXI deficiency includes FFP, antifibrinolytic agents [29], FXI concentrates (not available in the United States), and rFVIIa (not FDA approved for this purpose) [30]. There is concern of a prothrombotic potential associated with FXI concentrates as DIC and arterial thrombosis have been described in up to 10% of patients. Heparin has been added to these concentrates to reduce this thrombotic potential, but there is a general recommendation to maintain FXI levels at no greater than 70 IU per dL [30].

Factor XIII Deficiency

The most common presentation for FXIII-deficient patients is umbilical stump bleeding, but FXIII-deficient patients may also experience ICH, hemarthrosis, menorrhagia, and increased bleeding following surgery or trauma [31]. FXIII has a half-life of 8 to 12 days, and levels required to maintain hemostasis are only in the range of 2% to 5%. Treatment includes FXIII concentrates, FFP, or cryoprecipitate. Given FXIII’s long half-life, factor concentrates may be given once every several weeks as prophylactic therapy [17].

Vitamin K-Dependent Factor Deficiencies

Patients with combined deficiency of the vitamin K-dependent factors (FII, FVII, FIX, FX, proteins C and S) may present with umbilical stump bleeding or ICH [32]. Factor activity levels are variable and generally range from 1% to 30%. High doses of supplemental vitamin K may significantly improve or completely correct deficient factor activities. In acute bleeding episodes, patients may be treated with FFP or PCCs.

Congenital Qualitative Platelet Disorders
Defects in Platelet Adhesion

Bernard–Soulier syndrome (BSS) is a rare, autosomal recessive, severe bleeding disorder characterized by thrombocytopenia, giant platelets, and severe mucocutaneous bleeding [19]. Deficient platelet binding to subendothelial vWF is caused by abnormalities (either qualitative or quantitative) in the GP Ib/IX/V complex. The mainstay of treatment in BSS is platelet transfusion during clinically significant hemorrhagic episodes. However, alloimmunization to transfused platelets is often encountered when patients develop neutralizing antibodies to GP Ib/IX/V on transfused platelets which renders those platelets useless. rFVIIa has been used to treat patients with these inhibitors and has proven successful in many cases [33].

Defects in Platelet Aggregation

Glanzmann thrombasthenia is a rare, autosomal recessive disorder characterized by absent platelet aggregation secondary to defective GP IIb/IIIa on the platelet surface. Affected patients present with severe to life-threatening mucocutaneous bleeding. Treatment includes platelet transfusion. However, many patients may become refractory as alloantibodies to transfused platelet forms. rFVIIa has been used to treat bleeding in this disorder [34].

Disorders of Platelet Secretion: The Storage Pool Diseases

Platelets contain two types of intracellular granules, alpha and delta (or dense), which are required for an optimal secondary wave of platelet aggregation. The gray platelet syndrome is the most common alpha granule storage pool disease (SPD) and may predispose to early onset myelofibrosis, a probable consequence of the impaired storage of growth factors such as platelet-derived growth factor [35]. Hermansky–Pudlak syndrome and Chédiak–Higashi syndrome are SPDs affecting dense granules [36]. The Hermansky–Pudlak syndrome is associated with oculocutaneous albinism and increased accumulation of an abnormal fat-protein compound, ceroid, in the reticuloendothelial system. The Chédiak–Higashi syndrome is characterized by oculocutaneous albinism, neurologic abnormalities, immune deficiency with a tendency to infections, and giant inclusions in the cytoplasm of platelets and leukocytes. The primary treatment for clinically significant bleeding in patients with SPDs is platelet transfusion.
ACQUIRED COAGULATION DISORDERS

Anticoagulant Drugs

Use of anticoagulants in the critical care setting is ubiquitous. The pharmacology, monitoring, and appropriate reversal of anticoagulant drugs are reviewed in detail in Chapter 110.

Generally, patients on anticoagulants who develop clinically insignificant bleeding may be closely monitored while the drug is continued; appropriate therapeutic monitoring (e.g., INR, aPTT, TT, anti-Xa) should also be obtained and followed closely. Major bleeding, except in rare instances, typically should prompt discontinuation of anticoagulant drugs. Consideration should also be given to holding subsequent doses or reducing doses based on laboratory or clinical evolution.

Heparins, Low-Molecular-Weight Heparins, and Fondaparinux

These agents, and management of associated bleeding complications, are discussed in Chapter 93.

Warfarin (Coumadin)

Given its widespread use, warfarin is a common cause of iatrogenic, serious bleeding that frequently requires critical care. Warfarin is an oral vitamin K antagonist that exerts its anticoagulant effects through inhibition of vitamin K-dependent γ carboxylation of the vitamin K-dependent factors (FII, FVII, FIX, and FX). γ carboxylation is required for these coagulation factors to become biologically active. Warfarin also inhibits γ carboxylation of the vitamin K-dependent regulatory proteins C and S. Treatment with warfarin reduces the biologically active levels of all these vitamin K-dependent factors, both procoagulant and anticoagulant. However, the net effect at steady state is anticoagulation. Given the half-life of the independent factors affected by warfarin, patients may become relatively prothrombotic in the first several days after warfarin initiation as proteins C and S are the first to become significantly reduced. This is the rationale for “bridging” with unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) for the first several days of warfarin administration to abrogate extension of existing thrombosis or development of new ones.

Warfarin is monitored via the PT and INR with a typical therapeutic
range of 2.0 to 3.0 but this is patient and indication specific [24]. At supratherapeutic doses, the aPTT may also become prolonged.

When asymptomatic, supratherapeutic anticoagulation with warfarin does not generally require treatment beyond reducing the dose or holding warfarin for a period of time to allow for correction in the INR. Consideration may also be given to administering a small dose of vitamin K (1 to 5 mg) which will significantly lower the INR within 24 hours, depending on the INR and clinical scenario. If the patient is experiencing significant or life-threatening bleeding, reversal of anticoagulation is indicated and accomplished by replenishing the vitamin K-dependent factors. This can be best achieved using the 4-factor PCC (Table 88.6).

</tbody>
</table>
PCCs are plasma-derived products enriched in vitamin K-dependent factors. The typical dose is 25 to 50 U per kg depending on the degree of anticoagulation. There are two types of PCCs available, activated PCC (aPCC) and nonactivated (simply referred to as PCC). The activated form contains activated coagulation proteases that are used in the treatment of hemophilia with inhibitors. The nonactivated formulations were originally licensed for the treatment of hemophilia B, given their high FIX content. Furthermore, there are two types of nonactivated PCCs: a 4-factor (FII, FVII, FIX, FX)–containing product and 3-factor (FII, FIX, FX) products. Although the 3-factor products do contain some FVII, it is at a low concentration (less than one-third that of FIX) and therefore is considered a 3-factor concentrate. Recently, a 4-factor PCC was approved for reversal of oral vitamin K antagonist–induced bleeding. Both activated and nonactivated PCCs contain heparin and are therefore contraindicated in patients with heparin–induced thrombocytopenia [24]. As the effects of FFP, PCC, and rFVIIa are transient, 10 mg of parenteral vitamin K (IV over 30 minutes) should also be given to reverse the INR more durably. When available, PCCs are preferred over FFP because they are concentrated into much smaller volumes, can be virally inactivated, and have a lower risk of TRALI (see Chapter 89). The pharmacodynamics of warfarin is discussed further in Chapter 93.

Superwarfarins

The superwarfarins are a group of pharmacologic compounds that are long-acting rat poisons. They have considerably longer half-lives than warfarin (weeks to months vs. 1 to 2 days) and are considerably more potent. Superwarfarin poisoning has been associated with homicide and suicide attempts, accidental ingestion, and occupational exposure. Patients typically present with bleeding symptoms and laboratory findings similar to those of warfarin overdose; however, the PT/INR does not appropriately normalize with standard doses of vitamin K. An assay for each of the superwarfarins is necessary to confirm the diagnosis. Patients require high doses of vitamin K for prolonged periods to control
bleeding risk. FFP or PCCs may be required in episodes of life-threatening bleeding [25].

**Direct Thrombin Inhibitors (Argatroban, Bivalirudin, and Dabigatran)**

Reversal of anticoagulation due to direct thrombin inhibitors (DTIs) in cases of clinically significant bleeding is typically achieved through cessation of drug given a short half-life (<1 hour). A specific reversal agent for dabigatran has been approved for use in bleeding patients or those who need urgent surgery. This agent, Idarucizumab, is a F(ab)2 against dabigatran, which binds and clears active drug from the circulation. The pharmacodynamics of DTIs is discussed in greater detail in Chapter 93.

**Vitamin K Deficiency**

Vitamin K deficiency is a frequently encountered problem in hospitalized medical patients. It is particularly common in those with chronic malabsorption syndromes (e.g., cystic fibrosis), malnutrition, and those on broad-spectrum antibiotics [37]. Patients on warfarin and with vitamin K deficiency present with similar laboratory and physical findings, namely prolongation primarily of the PT as well as easy bruising or soft tissue bleeding. Vitamin K deficiency is managed by supplementation of vitamin K. If a patient has a malabsorptive syndrome, parenteral vitamin K is typically recommended.

As vitamin K-dependent coagulation factors are synthesized in the liver, it can be difficult to distinguish between vitamin K deficiency and a coagulopathy of liver disease (decreased hepatic synthesis of coagulation factors). In clinical scenarios where underlying liver disease is present, it may be beneficial to evaluate coagulation factor levels, both vitamin K dependent and independent (e.g., FII and FV, respectively). In this example, if both FII and FV levels are decreased, then the patient likely has hepatic synthetic dysfunction. If FV is normal and FII is decreased, then the patient likely has vitamin K deficiency.

**Coagulopathy of Liver Disease**

An unfortunate hallmark of liver disease is coagulopathy. It stands to reason that as all of the coagulation factors (except FVIII, which is also
synthesized in extrahepatic endothelial cells) are made in the liver, end-stage liver disease (ESLD) is marked by multiple coagulation factor deficiencies [38]. However, increased extravascular redistribution and increased factor consumption also contribute. The degree of coagulation factor reduction as well as the number of factors reduced typically parallel the severity of liver disease. Factors V and VII appear to be sensitive markers of hepatic synthetic dysfunction with FVII levels typically the most notably affected secondary to its short half-life [39]. A prolongation in the PT is therefore an early marker of liver disease. As hepatic dysfunction progresses and other coagulation factors in the common and contact activation pathway are decreased, the aPTT prolongs. In contrast, FVIII levels are typically elevated in compensated cirrhosis. This may be secondary to an increase in vWF that is seen in cirrhotics. In addition, proteins required for FVIII clearance such as low-density lipoprotein receptor-related protein are present in decreased amounts, thus raising FVIII levels. Patients with liver disease may have normal fibrinogen levels, given its long half-life, but they may develop an acquired dysfibrinogenemia associated with abnormal fibrinogen glycosylation that disrupts fibrin polymerization. This may be reflected by a normal fibrinogen quantitative assay but an abnormal functional assay such as the TT or RT.

In addition to coagulation factor deficiency, a number of other variables associated with advanced liver disease may contribute to coagulopathy in this population. These include (a) vitamin K deficiency secondary to malnutrition, malabsorption/maldigestion from bile salt insufficiency, and altered intestinal motility; (b) portal hypertension with resultant hypersplenism and secondary thrombocytopenia; (c) decreased thrombopoietin (the principal regulator of platelet production) synthesis by hepatocytes with resultant thrombocytopenia; (d) impaired platelet function as demonstrated by abnormal platelet function, as assessed by PFA-100; and (e) hyperfibrinolysis secondary to impaired synthesis of plasminogen activator inhibitors and decreased clearance of plasminogen activators. Chronic, low-grade DIC may also contribute to coagulopathy (discussed later).

Despite evidence for a significant coagulopathy based on laboratory tests as well as evident petechiae, ecchymosis, purpura, and bleeding after invasive procedures, patients with ESLD rarely bleed spontaneously. It is much more common for them to present with hemorrhage as a result of an underlying anatomic lesion such as from an esophageal varix. There remains active debate as to the actual net degree of coagulopathy in these patients. For instance, Mannucci has argued that defects in platelet number and function may be balanced by increased levels of vWF. Furthermore, decreased levels of coagulation factors and inhibitors of fibrinolysis are balanced by decreased levels of inhibitors of coagulation
and profibrinolytic factors [40]. The end result is a potential rebalancing of hemostasis. The fact that the degree of PT and aPTT prolongation correlates poorly with bleeding after liver biopsy and other potentially hemorrhagic procedures supports this rebalancing notion [41,42]. Ultimately, a more comprehensive assessment of hemostasis is needed as PT and aPTT only assess thrombin generation in a closed system devoid of anticoagulant factors and do not address fibrinolysis at all.

Given that we lack a comprehensive hemostatic assessment tool, many physicians prefer to prophylactically give FFP or other hemostatic agents to patients with ESLD who are to undergo procedures or who have significantly abnormal coagulation laboratory values. Unfortunately, we have little data to support these measures. The current guidelines recommend FFP transfusions only when hemostasis is needed for bleeding or invasive procedures and the PT or aPTT is >1.5 times normal (reviewed in reference [43]). FFP is generally given at a dose of 10 to 15 mL per kg repeated every 8 hours. Notably, despite repeated infusions of FFP, the PT may not completely correct and therefore clinical response should be monitored rather than relying on the PT as a measure of efficacy. As discussed earlier, patients with ESLD may also develop hypofibrinogenemia or a dysfibrinogenemia. This should be suspected in a patient with a prolonged TT or RT or in a patient who continues to bleed despite FFP infusion. Cryoprecipitate may be required to treat hypo/dysfibrinogenemia as FFP typically does not sufficiently replace fibrinogen. Cryoprecipitate is typically given in doses of 10 pooled units. Patients should be transfused to a goal fibrinogen level of >100 mg per dL. There are a number of human fibrinogen concentrates available in Europe, and in 2009 the Food and Drug Administration approved the first human fibrinogen concentrate in the United States. It is currently indicated for the treatment of patients with congenital afibrinogenemia and hypofibrinogenemia. Some authors have reported beneficial outcomes in patients given rFVIIa and PCCs in ESLD. However, there are currently no guidelines or randomized trials that address dosing or efficacy. However, given the hypervolemia typical of patients with ESLD, multiple infusions of FFP may not be possible and treatment with PCCs may be considered to reduce volume overload as well as decrease the risk of TRALI. Many have argued for controlled trials to evaluate the role of prophylactic hemostatic agents in this patient population as current practice typically involves using expert opinion and case series data.

Disseminated Intravascular Coagulation

DIC is a well-recognized syndrome characterized by both thrombotic and hemorrhagic complications in the setting of a number of defined disorders that are typically associated with systemic inflammation
The pathogenesis of DIC is complex and is characterized by widespread activation of the TF coagulation pathway with a marked imbalance between procoagulant and anticoagulant processes resulting in unopposed thrombin generation and diffuse fibrin clot formation with subsequent microvascular occlusion and tissue hypoxia [44]. When severe, these changes may culminate in multiple organ dysfunction syndrome.

The clinical presentation of DIC is variable and the majority of patients do not demonstrate a significant hemorrhagic phenotype. A clinical suspicion for DIC is paramount in establishing its diagnosis. In addition to a compatible underlying condition (e.g., sepsis), abnormal laboratory studies consistent with increased thrombin generation and fibrinolysis (consumptive coagulopathy) are also required. A DIC screening panel is typically composed of PT, aPTT, platelet count, fibrinogen, and D-dimer. DIC is suggested when the laboratories demonstrate increased activation of coagulation (elevated PT/aPTT, decreased fibrinogen) as well as evidence of fibrinolysis (elevated D-dimer or fibrin degradation products). An elevation in PT is a very sensitive measure of DIC but has lower specificity as it may be normal, especially in chronic DIC [44]. As fibrinogen is an acute phase reactant, it may be normal or even elevated in chronic DIC, thereby limiting its specificity in low-grade DIC. Elevation of D-dimer is a sensitive marker for DIC, in the range of 90% to 100% in one report; however, its specificity limits its utility as a single screening test [45].

The International Society on Thrombosis and Hemostasis established a subcommittee on DIC to develop and validate a scoring system to aid in the diagnosis of DIC. This system is based on platelet count, fibrin degradation products, PT, and fibrinogen level [46]. A prospective validation study demonstrated this scoring system to be 91% sensitive and 97% specific for the diagnosis of DIC, with higher scores correlated with higher 28-day mortality (Table 88.8) [47].

</table>
Identification and treatment of the underlying disorder remains the hallmark of treatment for DIC. Treatment of DIC should be based on both the clinical presentation as well as the laboratory results. Recommendations for the management of DIC are based on expert opinion given a lack of published, randomized data. In general, patients who experience significant bleeding or who require invasive procedures should be treated with FFP to replace coagulation factors. PCCs may also be considered when hypervolemia complicates FFP administration, but they may lack certain depleted factors such as FV [48]. Cryoprecipitate should be used to replace fibrinogen if the plasma level is <100 g per dL. Although there is no established threshold at which to transfuse platelets in DIC, in the setting of active bleeding or in anticipation of invasive procedures, platelet transfusions may be indicated.

In contrast to replacing coagulation factors, fibrinogen, and platelets, some investigators have evaluated the role of anticoagulants, namely UFH, in the treatment of DIC. This putative measure is based on the pathologic activation of coagulation associated with DIC as well as the depletion of endogenous anticoagulants. Initial animal studies evaluating
anticoagulants in DIC suggested a benefit [49]; however, subsequent human trials have yielded conflicting results [50,51]. To date there are no data from randomized, controlled trials to support the use of UFH in the management of DIC.

DIC is discussed in further detail in Chapters 91 and 94.

Trauma-Induced Coagulopathy

Trauma-induced coagulopathy includes the coagulopathy associated with the stresses of trauma as well as unintended consequences of its treatment. Historically it was felt that the coagulopathy associated with trauma was largely secondary to dilution of the coagulation system with volume and blood replacement. However, it is becoming increasingly apparent that this process is much more dynamic and complicated. Traumatic events requiring massive transfusion of blood lead to significant coagulopathy through a number of mechanisms that include (a) dilution of coagulation proteins and platelets from volume resuscitation, (b) consumptive coagulopathy and thrombocytopenia (through DIC associated with trauma), (c) acidemia which impairs function of the coagulation cascade, (d) hypothermia which impairs function of platelets and coagulation factors, and (e) electrolyte perturbations, particularly hypocalcemia which impairs the calcium-dependent coagulation processes [52]. Prompt attention is required to mitigate the coagulopathy associated with trauma and to rapidly correct it. Clinically, patients have a compatible history of massive trauma requiring aggressive resuscitation and typically have a prolongation of PT and aPTT that corrects on mixing study, as well as thrombocytopenia and often hypofibrinogenemia. Treatment is targeted at correcting or preventing the occurrence of the aforementioned mechanisms that have been associated with the development of trauma-induced coagulopathy. Most guidelines recommend transfusion of red blood cells to a target hemoglobin of 7 to 10 g per dL to maintain rheology, FFP administration to a goal PT/aPTT of <1.5 × upper limit of normal, platelet transfusion to keep platelets >50 × 10^9 per L (or >100 × 10^9 in patients with brain injury), and fibrinogen >100 mg per dL [53]. More recently, ratio-driven transfusion protocols utilizing equal volumes of FFP, packed red cells, and platelets have been utilized to treat hemorrhagic shock in both trauma and non-trauma patients [54]. The use of factor concentrates (fibrinogen, PCCs) to target specific phases of coagulation may offer benefit over blood product ratio-driven transfusion. The outcome benefit of factor concentrates, however, has not yet been demonstrated in well-powered prospective trials [55].
Acquired Hemophilia A

The most common antibodies that affect clotting factor activity with a resultant hemorrhagic phenotype are directed against FVIII. Acquired hemophilia A, or acquired FVIII deficiency, is a rare disorder with an estimated incidence of 1.0 per million that is caused by autoantibodies directed against a patient’s endogenous FVIII, resulting in low FVIII activity levels [56]. Acquired hemophilia A is most commonly an idiopathic condition that occurs in the elderly but can also be associated with malignancy, drugs, autoimmune disorders, and the postpartum state.

Acquired hemophilia should be suspected in patients without a prior bleeding history who present later in life with significant, large ecchymoses, hematomas, mucosal, gastrointestinal bleeding, or who experience significant bleeding following surgery or trauma. Hemarthroses that are a hallmark of congenital hemophilia are not typical of acquired hemophilia.

Patients with acquired hemophilia present with bleeding symptoms and a prolonged aPTT in contrast to patients with a lupus anticoagulant who typically present with a prolonged aPTT and thrombotic complications [57,58]. Once acquired hemophilia is suspected based on clinical presentation and a prolonged aPTT, an incubated aPTT mixing study should be performed. As FVIII inhibitors are commonly time and temperature dependent, the mixing study should be performed at 37°C for 1 to 2 hours. In the case of an acquired FVIII inhibitor, the incubated aPTT will not completely correct into the normal range which indicates the presence of an inhibitor. A FVIII activity level may also be helpful to identify the inhibitor as FVIII specific. The strength of the inhibitor may be quantified in a Bethesda assay. The strength of the inhibitor has treatment implications.

Treatment goals of these patients are twofold: (a) control of bleeding and (b) eradication of the inhibitor. Bleeding in patients with low-titer inhibitors (<5 BU) can often be treated with high doses of FVIII concentrates. Bleeding in patients with high-titer inhibitors is treated with a FVIII inhibitor bypassing agent, such as an aPCC or rFVIIa [59,60]. Recombinant porcine FVIII has been recently approved for treatment of acquired hemophilia [61]. Inhibitor eradication typically involves immunosuppression, though spontaneous resolution of the inhibitor can occur [62,63].
ACQUIRED PLATELET DISORDERS/DYSFUNCTION

Medications

The antiplatelet effect of medications is the most common cause for acquired platelet dysfunction. Aspirin and nonsteroidal antiinflammatory drugs (NSAIDs) are the most commonly used medications that affect platelet function (Table 88.9) [64]. Their predominant antiplatelet effect is achieved through the inhibition of platelet cyclooxygenase (COX-1) which in turn ultimately inhibits vasoconstriction and platelet aggregation. Inhibition of COX-1 by aspirin is irreversible for the life of the platelet and is dose dependent. There is an increased risk of bleeding in patients taking aspirin, and two meta-analyses described an approximate 1% increase in absolute risk of bleeding in patients taking aspirin compared to placebo [65,66]. Notably, this bleeding risk does not appear to be dose dependent when the total daily dose is ≤325 mg per day but does increase with concomitant administration of other anticoagulants or antiplatelet agents [67,68]. The primary site of bleeding associated with aspirin is gastrointestinal. NSAIDs, on the other hand, reversibly inhibit COX-1 for the length of time that the medication remains metabolically active. Platelet function is not substantially affected by the COX-2 specific inhibitor, celecoxib, or acetaminophen.

Dipyridamole is a less frequently used antiplatelet drug with an unclear mechanism of action. It has historically been used for stroke prophylaxis. There does not appear to be a significant increase in bleeding risk for patients taking dipyridamole versus placebo in several randomized trials evaluating the efficacy of dipyridamole in stroke prevention [69].

Clopidogrel (Plavix), ticlopidine (Ticlid) and prasugrel (Effient) belong to a class of antiplatelet agents known as the thienopyridines and are in the treatment of cardio- and cerebrovascular disease. Thienopyridines are irreversible antagonists to the platelet P2Y12 receptor which inhibits ADP-mediated platelet aggregation. The thienopyridines, particularly ticlopidine (Ticlid), have been implicated in the development of thrombotic thrombocytopenic purpura [40]. Ticagrelor (Brilinta) is often listed with thienopyridine inhibitors and has similar indications for use but is not a thienopyridine. It is a cyclo-pentyltriazolo-pyrimidine that reversibly inhibits the P2Y12 receptor.

The GP IIb/IIIa antagonists are a group of antiplatelet agents that are primarily used during coronary procedures. These drugs impair aggregation by inhibiting the cross bridging of platelets by fibrinogen. This class is associated with an increased risk of bleeding, particularly at the puncture site for percutaneous coronary intervention. There does not appear to be an increased risk for intracerebral hemorrhage for patients receiving GP IIb/IIIa inhibitors versus heparin [70]. These agents are also associated with thrombocytopenia, often profound, that may result
in significant bleeding complications [71].

Many other medications including large doses of penicillins, psychotropic drugs such as fluoxetine, dietary supplements such as fish oil, gingko, garlic, and cumin may impair platelet function, although not typically to a significant degree [72].

Laboratory testing to confirm an acquired platelet defect secondary to medication is rarely necessary as clinical history and medication record usually suffice. However, if needed for confirmation, platelet function testing may be useful. Treatment for drug-induced platelet dysfunction depends on the severity of bleeding as well as the medication involved. In most cases, minor bleeding may be addressed by withholding the medication. In more severe cases, platelet transfusion may be indicated depending on timing of the last dose as well as its specific platelet effect. In general, platelets have an average life span of 7 to 10 days. As a result, the bone marrow replaces approximately 10% of the body’s platelets each day. Therefore, if a medication irreversibly inhibits platelet function, platelet transfusion may be needed to reverse the antiplatelet effect until the bone marrow has sufficiently replenished the affected platelets. For most situations, a single platelet transfusion is sufficient to correct bleeding association with disordered platelets.

Acquired platelet dysfunction due to antiplatelet agents is discussed in further detail in Chapter 91.

Uremia

The multisystem organ dysfunction encountered in critically ill patients often includes acute kidney injury and subsequent uremia. Bleeding associated with uremia has long been recognized and has historically been associated with a prolonged BT. However, the degree of BT prolongation neither correlates with the degree of azotemia nor the severity of bleeding symptoms. The clinical manifestations of uremic bleeding are predominantly mucocutaneous, though patients may present with epistaxis, gastrointestinal bleeding, hematuria, or increased bleeding following surgery or procedures.

Despite this long-recognized association between uremia and a bleeding diathesis, the exact pathophysiology remains poorly defined, though impairment in platelet function appears integral [73]. There are data to suggest that this is a multifactorial process and includes an acquired platelet defect as well as impairment in platelet–endothelium interaction. Additional factors include vWF abnormalities, anemia which
affects rheology, thrombocytopenia, uremic toxins, and increased nitrous oxide (NO) production [74]. The presence of a uremic toxin is supported by the improvement in platelet function in patients following dialysis. Notably, urea is unlikely to be the primary toxin as there is no positive correlation between blood urea nitrogen and bleeding risk [75].

Treatment for uremic bleeding often includes aggressive dialysis which may correct the bleeding and has been suggested to prevent uremic bleeding [76]. DDAVP has been recommended as the first-line therapy for uremic bleeding (2 to 4 µg per kg intranasally or 0.3 µg per kg by slow intravenous infusion); it improves platelet function in uremia, most likely due to release of FVIII and vWF [77]. If no improvement is noted after the first dose, further doses should not be given. If DDAVP is ineffective or contraindicated, cryoprecipitate may be given (10 units every 12 to 14 hours). Improvement in bleeding in response to cryoprecipitate is likely related to FVIII and vWF [78]. Correction of anemia to a goal hematocrit of 30% corrects the BT in many patients through improved rheology. This may be accomplished via red cell transfusions in the acute period or erythropoietin over prolonged periods. Erythropoietin may also have beneficial effects on platelet function [79]. Conjugated estrogens may improve uremic bleeding and appears to do so in a dose-dependent manner presumably by reducing NO production (reviewed in reference [76]).

Hematologic Disorders

Abnormal platelet function is frequently noted in patients with a number of primary hematologic disorders, including myelodysplastic syndromes and myeloproliferative disorders. The bleeding diathesis occurs out of proportion to that expected in patients with similar quantitative platelet defects. In general, the mechanisms underlying the platelet dysfunction seen in these disorders are poorly understood but probably reflect the genetic and developmental abnormalities in stem cells that underlie these disorders. The severity of the predisposition to bleeding cannot be reliably predicted from the results of the BT, platelet count, or in vitro platelet function tests.

The bleeding complications of the myeloproliferative disorders have been estimated in the literature to range from 1.7% to 37%, depending on the disorder and population screened [80]. The bleeding manifestations in both polycythemia vera and essential thrombocytosis involve the skin and mucous membranes and include menorrhagia, epistaxis, ecchymosis, and gastrointestinal bleeding. This pattern of bleeding suggests an underlying platelet or vWD defect. It has long been assumed that dysfunctional platelets derived from abnormal stem cells were responsible for increased bleeding with these disorders. Extreme
thrombocytosis has been recognized to paradoxically result in an acquired type 2 vWD which contributes to the bleeding diathesis [81]. Other conditions associated with acquired vWD include Heyde’s syndrome, which is the association of tight aortic stenosis with gastrointestinal arteriovenous malformations. In this condition, the shear stress associated with the stenotic aortic valve consumes the HMW multimers of vWF [82]. The pathophysiology is the same in bleeding patients with left ventricular assist devices [47].

Treatment of the underlying disorder remains the mainstay, though platelet transfusions may be needed for clinically significant bleeding. If acquired vWD is suspected, it should be confirmed through appropriate testing (to be discussed later) prior to initiating directed treatment. Treatment depends largely on the degree of defect and could include intravenous immune globulin, DDAVP, or vWF replacement [83].
OTHER ACQUIRED BLEEDING DISORDERS

Acquired vWD

Acquired vWD is a heterogeneous disorder that is associated with a number of different disease states. Several distinct pathophysiologic mechanisms are involved which include increased vWF clearance or proteolysis, vWF adsorption to cells with subsequent increased clearance, decreased synthesis, and antibody formation against vWF [83]. Lymphoproliferative and autoimmune disorders are most commonly associated with acquired vWD.

In general, mechanisms underlying acquired vWD are divided into immune- and nonimmune-mediated categories. Immune-mediated acquired vWD is suggested by mixing studies which show an inhibition of vWF in a functional assay. Proposed nonimmune mechanisms include (a) vWF being adsorbed onto cells (e.g., Wilm’s tumor, platelets in myeloproliferative disorders, plasma cells in multiple myeloma, and Waldenström’s macroglobulinemia); (b) increased proteolysis of HMW multimers at sites of high blood shear flow rates in patients with aortic stenosis, angiodyplasia, and congenital heart disease; (c) decreased synthesis in hypothyroidism; and (d) proteolysis by plasmin during increased periods of fibrinolysis such as with thrombotic therapy and DIC. A diagnosis should be expected if a patient has a bleeding phenotype similar to a patient with vWD, a compatible underlying disorder, an absence of lifelong bleeding symptoms, and a negative family history [84]. Treatment for acquired vWD is aimed at correcting the underlying disorder if possible and promoting hemostasis as one would in patients with congenital vWD (e.g., DDAVP, factor concentrates, antifibrinolytics).

Acquired FII (Prothrombin) Inhibitors

Clinically, patients with antiphospholipid antibodies most commonly have a thrombotic phenotype; however, rarely these patients may also have an antibody directed against prothrombin. This antibody binds to prothrombin and increases its clearance, which results in low FII activity levels and clinically significant bleeding. This disorder should be considered in a bleeding patient with evidence for prolongation in PT and PTT. The PT should correct with mixing, the PTT will not. Tests for the
lupus inhibitor will be positive, and measurements of FII activity as well as FII antigen will be low. Treatment for acute hemorrhage involves FFP, typically at a dose of 15 to 20 mL per kg with a goal FII activity of >30%. PCCs may also be used [85].

Acquired FV Inhibitors

Acquired FV inhibitors in the past were noted to occur most frequently following exposure to topical bovine thrombin or fibrin-glue preparations. These preparations were contaminated with bovine FV and antibodies cross-reacted with human FV. These preparations are no longer used. A systematic review showed that acquired FV inhibitors now occur more commonly in conjunction with autoimmune disorders, cancer, and drugs [86]. Patients typically present with a significant prolongation in both the PT and PTT. This prolongation fails to correct in a mixing study. Inhibitor specificity to FV is demonstrated with a low FV activity. FFP is not recommended as a treatment as FV is present in such a low concentration that it is quickly neutralized by the inhibitor. PCCs are likewise felt to be unhelpful given their low FV content. Plasma exchange and platelet transfusions have been used successfully to control bleeding. It is thought that FV contained in the alpha granules of circulating platelets is protected from inhibition until the platelet becomes activated at the site of vessel damage. rFVIIa has been reported to successfully promote hemostasis.

Acquired FX Deficiency

Acquired FX deficiency is associated with amyloidosis. It is thought that amyloid fibrils bind to FX and thereby remove it from circulation. Treatment of the underlying amyloidosis and/or splenectomy has been shown to improve the circulating FX level [87]. PCCs are the preferred treatment for acute bleeding episodes, and pharmacokinetic studies should be done on each individual to provide guidance as to optimal dose and interval [88].
REFERENCES

Transfusion support can be a key element in decreasing morbidity and mortality of the critically ill patient by the support of oxygen delivery and correction of hemostatic abnormalities. An understanding of the benefits, limitations, and risks of blood component therapy is of fundamental importance in the intensive care setting. This chapter outlines blood components available for transfusion, their appropriate dosages, and therapeutic effects. Complications of transfusion therapy, including infectious risks, transfusion reactions, effects of storage, and immunomodulatory effects, as well as methods to minimize these complications, are also discussed.

BLOOD COMPONENT THERAPY

Cellular Blood Components

Red Blood Cells

A thoughtful transfusion policy depends on the time the anemia developed over and can be expected to continue; additional medical problems that may make a patient more susceptible to anemia, such as tissue ischemia and pulmonary disease; and whether there is rapid, ongoing blood loss.

One unit of “packed” red blood cells (pRBCs) is processed by the removal of platelet-rich plasma from a donated unit of whole blood and contains approximately 200 mL RBCs, usually less than 50 mL plasma,
and an additive that brings the component to 300 to 350 mL in total volume. Depending upon the additive, the storage life at 4°C will be from 35 to 42 days. RBC storage has multiple theoretic and measurable effects. Any platelets still present in the component are rendered inactive by the cold storage. As RBCs are stored, intracellular potassium leaks into the plasma space. 2,3-Diphosphoglyceric acid (2,3-DPG) may also be depleted from the RBCs, which theoretically could cause increased oxygen affinity and decreased release of oxygen at the tissues [1]. This effect reverses after several hours in vivo, but may be clinically significant in the patient undergoing massive transfusion. Stored pRBC also have elevated plasma ammonia levels, elevated pCO₂, lowered pH, and increased amounts of microaggregates, and the RBCs undergo changes in shape and deformability, thereby making transit through small vessels more difficult. These all have theoretic effects on oxygen delivery when given rapidly in large amounts. Massive transfusion can also theoretically result in hypocalcemia and hyperkalemia.

In 1993, Marik and Sibald [2] reported the incidental finding of increased gastric pH in 23 patients with septic shock transfused with 3 units of pRBC, but Walsh failed to find a similar effect in a small randomized control trial in 22 patients with septic shock transfused with pRBC stored for <5 or >20 days [3]. Since that time, small prospective trials and retrospective studies examining the effects of RBC age at transfusion have yielded conflicting results [4–6]. A prospective, blinded randomized trial of 2,400 critically ill patients comparing RBCs stored for less than 8 days or standard issue (mean 22.0 ± 8.4 days) showed no difference in 90-day mortality nor adverse outcomes between the groups [7]. A prospective trial in nearly 1,100 patients undergoing complex cardiac surgery randomized patients aged 12 years or older to receive red cells stored for 10 days or less or 21 days or more [8]. No difference between the groups was found in Multiple Organ Dysfunction Score, 7- and 28-day mortality or adverse events, although hyperbilirubinemia was more common in the longer term storage group. The effect of storage age remains controversial, particularly in neonates and pediatric patients [9] and will require additional prospective randomized clinical trials before the true clinical significance of storage age and the nature of the effect becomes clear [10].

Other than factors V and VIII, the activity of most coagulation factors are quite stable during storage, even after 2 weeks, and, therefore, whole blood (without the plasma removed), when available, may be used in selected patients with coagulopathy and bleeding, and can reduce donor exposure by limiting administration of multiple products (e.g., red cells and plasma) during massive transfusion [11]. Factor V levels in stored whole blood are well above 50% and, therefore, adequate for hemostasis. Factor VIII is produced by endothelial cells as well as by the liver, and the
levels increase in the setting of inflammation, so a decrease with storage may be less clinically relevant. Whole blood may also be the preferred form of red cell transfusion in patients who require intravascular volume expansion as well as increased oxygen-carrying capacity.

The primary function of hemoglobin in RBCs is to transport oxygen efficiently from the lungs to the various tissues of the body. Oxygen transport is a complex process regulated by several control mechanisms, involving the heart and vascular system. The most important functional feature of the hemoglobin molecule is its ability to combine loosely and reversibly with oxygen. Decreased hemoglobin oxygen affinity and increased tissue oxygen delivery occurs with increased temperature and decreased pH, when there are increased tissue requirements. Oxygen is also less tightly bound when 2,3-DPG levels are increased, which are increased in chronically ill patients [12]. In the seriously ill patient with severe acidosis and septic shock, however, 2,3-DPG levels may decrease, resulting in decreased tissue oxygen delivery.

**Transfusion Threshold.** In A Normovolemic, Otherwise Healthy Individual, The Effect of A Decreased Hematocrit Is Decreased Blood Viscosity and A Compensatory Augmentation of Cardiac Output and Blood Flow To Most Organs [13]. Human and Animal Studies Reveal Remarkable Tolerance For Hematocrit Levels As Low As 15% [14,15], But an Optimum Value Has Not Been Well Defined and Is Very Dependent on The Patient’s Physiologic State. Advocates of Restrictive Transfusion Strategies Point Out That Transfusing To Normal Hemoglobin Concentrations Does Not Improve Organ Failure and Mortality In The Critically Ill Patient [16] And, To Data, Suggesting Transfusion May Actually Be Associated With Increased Infection Rates, Morbidity, and Mortality [17]. The Proponents of More Liberal Transfusion Strategies Point Out The Possible Detrimental Effects That May Be Associated With Oxygen Debt [18].

A decrease in the hematocrit also involves a redistribution of blood flow away from the endocardium and may have adverse effects on ischemic cardiac tissue. Postoperative patients with known vascular disease and hematocrits <28% have been shown to have a significant increase in myocardial ischemia and morbid cardiac events [19], and in one study that retrospectively evaluated patients refusing transfusion on religious grounds, low preoperative hemoglobin was associated with increased morbidity and mortality in patients with cardiovascular disease undergoing surgery [20]. However, in a large multicenter, randomized trial, there were no differences in adverse outcomes when patients with cardiac disease were transfused at a hemoglobin threshold of 7.0 versus 10 g [21]. In this study of more than 800 patients, less acutely ill, younger patients (<55 years of age) without cardiac disease who were randomized
to the more liberal (higher) transfusion trigger had a higher overall mortality rate. A restrictive RBC transfusion strategy also did not adversely affect outcomes related to mechanical ventilation [22]. In postoperative patients without cardiovascular disease, few studies support interference with wound healing or increased anesthesia risk at hemoglobin levels of <10 g per dL [23], and hemoglobin values as low as 7 g per dL, appear to be safe in otherwise healthy individuals [24].

A systematic review of 11 observational studies of RBC transfusion involving more than 290,000 patients with acute coronary syndromes suggested that transfusion thresholds less than 8 g per dL of hemoglobin appeared to be beneficial or, at worst, neutral, whereas there was a suggestion of harm when transfusion was undertaken at hemoglobin levels above 11.0 g per dL. Elderly patients with known cardiovascular risk factors undergoing hip surgery do not experience improvements in mortality, in-hospital morbidity, or mobility when transfused at a hemoglobin threshold of 10 versus 8 g per dL [25]. A prospective randomized trial of 2,000 patients in the United Kingdom compared a hemoglobin transfusion threshold of <9 g per dL to a threshold <7.5 g per dL [26]. Although there were more deaths in the restrictive-threshold group (4.2% vs. 2.6%; hazard ratio, 1.64; 95% confidence interval, 1.00 to 2.67; \( p = 0.045 \)), the primary outcomes of serious infection or an ischemic event did not differ between the groups. Further study in this patient population is needed to determine optimum transfusion thresholds, particularly in the setting of cardiac surgery and intracardiac devices and major vascular surgery where perioperative transfusion may be independently associated with increased morbidity and mortality [27].

Other patient populations have specifically been evaluated in prospective randomized trials for optimum hemoglobin threshold for red cell transfusion. Restrictive transfusion thresholds of <7.0 g per dL were not associated with increased mortality or adverse outcomes in patients with septic shock [28] and significantly improved outcomes in patients with acute upper gastrointestinal bleeding [29]. Studies in animal models [30] and in humans [31,32] reveal that platelet function and interaction with subendothelium decline at lower hematocrits; however, whether higher hematocrits protect against bleeding in the thrombocytopenic or thrombocytopathic (e.g., uremic) patient is not known and that further studies are needed [33].

Blunted erythropoietin responses have been noted in critically ill pediatric [34] and adult patients [35]. Long-term intensive care patients may not only fail to increase their erythropoietin level in response to
anemia, but may have correctable nutritional deficiencies and iron profiles consistent with anemia of chronic disease. Although erythropoietin therapy increases RBC production and appears to decrease transfusion needs [36–38], the effect can take weeks and may reduce blood cell transfusion only minimally. It is an expensive alternative to more restrictive transfusion strategies to reduce transfusion exposure in appropriately chosen patients.

**Therapeutic Effects.** The Response To Red Cell Transfusion Will Depend on Intravascular Volume, But It Can Be Estimated That 1 Unit of Prbcs Will Increase The Hematocrit by Approximately 3%. It May Take Up To 24 Hours While Intravascular Volume Equilibrates For Full Effect. A Stable Patient Should Be Transfused Only 1 Unit of Red Cells Before Rechecking. Rapid Ongoing Red Cell Destruction or Splenic Sequestration May Also Affect Hematocrit Increment and Red Cell Survival.

**Emergency Blood Usage.** Uncrossmatched Type O Rbcs Can Be Used For A Bleeding Patient When It Is Judged To Be Life- or Organ Saving. Type O, Rh-negative Rbcs Can Be Transfused To People of Any Blood Type With Only A Slight Risk of Hemolysis. This Risk Increases In Patients Who Have Previously Been Transfused or Pregnant and May Have Formed Antibodies [39]. Type O, Rh-positive Rbcs Are Sometimes Used For Women Who Are Beyond Childbearing Age and In Adult Males. When Rh-positive Rbcs Are Used In an Rh-negative Patient, There Is A Chance of A D Immunization, and If The Patient Requires Emergency Transfusion In The Future, They May Have Preformed Antibodies. Anti-d Antibodies Do Not Generally Cause Immediately Intravascular Hemolysis, But Rather A Slow Extravascular Hemolysis With Relatively Low Risk. Anti-rhd (rhogam) May Be Given Within 48 Hours of Giving Transfusion of Rh-positive Blood To an Rh-negative Woman of Childbearing Age, But The Amounts Required Limit Its Use In Prevention of Alloimmunization. A Strategy of Equal Numbers of Red Cells Units To Plasma and Platelets (see “platelets” Section) Appears To Be Beneficial In The Resuscitation Of The Trauma Patient Requiring Massive Transfusion [40].

**Platelets**

Platelets are essential for the initial phase of hemostasis. Following exposure of subendothelial substances, platelets adhere to the subendothelial tissues by von Willebrand Factor and other adhesive proteins. This initial adhesion activates platelets, causing release of platelet $\alpha$ and dense granules. Some of these granule contents, including
Factor V, fibrinogen, von Willebrand Factor, and calcium, move to the extracellular space via the open canalicular system, increasing their concentrations in the immediate “neighborhood” of the platelet. With platelet activation, anionic phospholipids move to the outer membrane surface, forming binding sites collectively known as Platelet Factor 3, upon which coagulation factors can interact with calcium to form factors IXa, Xa, and thrombin. Glycoprotein IIb-IIIa is exposed and binds fibrinogen, forming links between platelets. Thrombin generation causes further platelet activation and converts fibrinogen to fibrin, resulting in a platelet-fibrin mass that can effectively cease bleeding from a break in the endothelium. Fifteen percent of the platelet’s protein is actin and myosin, coupling in the presence of increased concentrations of adenosine triphosphate and calcium, leading to cytoskeletal movement and clot retraction.

The threshold of thrombocytopenia at which bleeding may occur will vary depending on the patient’s clinical condition. In general, spontaneous bleeding does not occur until the platelet count falls below 5,000 to 10,000 per µL [41–44]. In a prospective clinical trial of 600 patients with hematologic malignancy, waiting to transfuse platelets therapeutically upon observation of bleeding is associated with increased bleeding [45]. The recommended “trigger” by the AABB for prophylactic platelet transfusions in patients undergoing chemotherapy or hematopoietic stem cell transplantation without bleeding or other comorbid conditions is <10,000 per µL [46]. Lower doses seem to be as effective in preventing bleeding as higher doses, but patients who receive smaller doses require more frequent transfusions, making this strategy less appropriate for outpatient transfusion [47]. For the majority of invasive procedures, including lumbar puncture, a platelet count of 30 to 50,000 per µL will be adequate. For high-risk procedures, such as neurologic or ophthalmologic surgeries, a platelet count of 100,000 per µL is recommended by the American Society of Anesthesiology [48]. Technique and experience appear to be as least important predictors of bleeding following placement of catheters as clotting abnormalities, even in patients with isolated platelet counts <20,000 per µL [49]. The risk of bleeding with thrombocytopenia increases when complicated by other hemostatic abnormalities.

Platelet counts less than 50,000 per µL are associated with increased risk of microvascular bleeding in the massively transfused patient [50]. For this reason, platelet transfusion has been advocated with replacement of every blood volume to avoid the effect of dilutional thrombocytopenia
In the pragmatic, randomized optimal platelet and plasma ratios (PROPPR) trial, platelet concentrates were transfused in equal numbers to units of red cells and plasma. However, it is important to note that up to six platelet concentrates or their equivalent are generally present in a platelet component prepared by the transfusion service. Therefore, one platelet transfusion should accompany every 5 or 6 units of red cells and plasma.

Higher transfusion triggers may be indicated with abnormal platelet function. Platelet function abnormalities may be congenital or acquired. Medications, sepsis, malignancy, tissue trauma, obstetric complications, and extracorporeal circulation may all adversely affect platelet function. Liver and kidney disease may be associated with severe thrombocytopenia. Hypothermia prolongs bleeding time in trauma patients and arterial hemorrhage in animals. Glycoprotein IIb-IIIa inhibitors may affect platelet number and function. If platelet dysfunction is present, the patient with a disrupted vascular system (e.g., trauma or surgery) will require a higher platelet count to achieve hemostasis. Higher counts may be necessary to prevent spontaneous bleeding as well. The transfused platelets may quickly become dysfunctional in the patient, and other therapy may be necessary, such as dialysis, desmopressin acetate (DDAVP) and estrogen for bleeding in renal failure, rewarming of the hypothermic patient, or correction of acidosis.

In several situations, platelet transfusions may not be indicated unless there is significant bleeding. In autoimmune thrombocytopenias (e.g., immune thrombocytopenic purpura and post-transfusion purpura), transfusion increments are usually poor, and platelet survival is short. Administration of intravenous immune globulin in high doses may improve transfusion response and survival, as well as treat the underlying disease. Because of reports of rapid exacerbation of the thrombotic process in the cerebrovascular circulation in patients with thrombotic thrombocytopenic purpura (TTP) following platelet transfusion and the association of arterial thrombosis and in-hospital mortality with platelet transfusion in a large retrospective study of patients with TTP or heparin-induced thrombocytopenia make platelet transfusions relatively contraindicated in TTP unless there is clinically significant bleeding.

Pooled random donor platelet concentrates are prepared from platelets that have been harvested by centrifuging units of donated whole blood. Up to 8 units of platelets, each from a separate donor, can be pooled into a single bag for transfusion. All units are from the same ABO type. If ABO compatible platelets are unavailable, in most cases, pooled ABO incompatible platelets can be substituted with very little risk. The usual adult dose is 1 unit per 15 kg of body weight for a bleeding patient.
In a 70-kg patient with a normal sized spleen, each unit is expected to increase the platelet count by approximately 7,000 per µL (Table 89.1) when checked 10 minutes to 1 hour after transfusion [59]. The survival of transfused platelets averages 3 to 5 days, but will decrease if a consumptive process is present. Platelet concentrates also contain about 60 mL of plasma per unit and small numbers of RBCs and leukocytes. Platelet units must be maintained at room temperature because platelets lose shape and release their granular contents when refrigerated. Apheresis platelets, collected from a single donor, are prepared in components equivalent to 4 to 6 pooled units. An apheresis platelet concentrate contains 200 to 400 mL of plasma and, if the plasma is of an incompatible type, may be reduced in volume by centrifugation, although this results in an approximate 10% to 15% loss of platelets and, probably, some loss of function. Apheresis platelets may be collected for a specific recipient from a family member or other human leukocyte antigen (HLA)-compatible donor for patients that have become refractory to random donor platelet transfusions owing to alloimmunization. Leukocyte reduction of transfused cellular blood components has been clearly shown to reduce the rate of alloimmunization in patients undergoing chemotherapy for acute myelocytic leukemia [60].

<sup>b</sup>Whole blood platelets. An apheresis platelet component contains the equivalent of 4–8 units of whole blood platelets.

Granulocytes
The degree of granulocytopenia is directly related to the risk of infection [61]. Although antibiotics have improved morbidity and mortality in patients affected by prolonged periods of neutropenia, most antimicrobials are less effective in the presence of granulocytopenia. Bacterial and, more particularly, fungal infections remain a major cause of death in hematopoietic stem cell transplantation patients despite shortening of the period of neutropenia with hematopoietic growth factors [62]. Granulocytes collected by continuous flow centrifugation and filtration leukapheresis function normally in vitro in the quantitative nitroblue tetrazolium, oxygen consumption, and chemotaxis assays [63]. Bacterial killing by filtration leukapheresis granulocytes, which circulate for several hours post-transfusion, is only slightly decreased compared to granulocytes collected by continuous flow centrifugation. Transfused granulocytes rapidly migrate to sites of infection [64].

Early studies showed promise for the use of granulocyte transfusion for treatment of documented infections in neutropenic patients [65–67]. However, their usefulness in the prevention of infection has been more controversial [68] owing to limitations in the inability to collect cells in sufficient amounts to provide an effective transfusion dose, poor response to granulocytes in heavily transfused, alloimmunized patients [69], and the early development of alloimmunization in patients transfused with granulocytes [70]. To this end, HLA-compatible donors have been administered corticosteroids prior to granulocyte collection with some limited success. The administration of granulocyte colony-stimulating factor (G-CSF) has been shown to be safe when given to normal donors [71] and has been administered to donors prior to collection to increase collection and post-transfusion increments [72]. A study of granulocyte transfusion from G-CSF–stimulated donors failed to show improvement in mortality when compared to no transfusion; however, when data from centers that collected higher doses of granulocytes were evaluated, there appeared to be a benefit [73].

Plasma Components

Plasma

One unit of plasma is the plasma taken from a unit of whole blood. It may be frozen within 8 hours of collection and contain all coagulation factors in normal concentrations. It is free of RBCs, leukocytes, and platelets. Plasma may also be provided as “frozen plasma” or “thawed plasma”.
These components are prepared by methods similar to plasma, and their factor concentrations differ only slightly. All will be considered here collectively as “Plasma.” One unit contains approximately 200 to 250 mL and must be ABO compatible (type AB is the universal donor type). Rh factor need not be considered. Because there are no viable leukocytes, plasma carries minimal risk of cytomegalovirus (CMV) transmission or graft-versus-host disease (GVHD).

Plasma transfusion is indicated in patients with documented coagulation factor deficiencies and active bleeding. Plasma should not be used to correct isolated deficiencies in clotting factors when a concentrated replacement source, such as factor VIII or IX, is available, because these concentrates are either recombinant or have undergone processing to inactivate viruses and can correct the deficiency using a much smaller infused volume. Factor deficiencies may be congenital or acquired, secondary to liver disease, warfarin anticoagulation, disseminated intravascular coagulation (DIC), or massive replacement with RBCs and crystalloid/collodion solutions. Usually, there is an increase of at least 1.6 times the normal prothrombin time (PT) or activated partial thromboplastin time (aPTT) before clinically important factor deficiency exists. This corresponds to levels of most factors <20% of normal. Above these levels, most routine nonmajor invasive procedures such as line placement, liver biopsy [74], and thoracentesis [75] are not associated with an increased risk of bleeding complications; however, the acceptable upper limits of PT and PTT prior to invasive procedures have not been evaluated in a large prospective randomized study to date [76–78].

In the massively transfused patient, consumption and dilution of coagulation factors may cause rapid development of coagulopathy. Patients with a PT or aPTT ratio (reference midrange normal value divided by actual) ≥1.8 had an 80% to 85% chance of exhibiting microvascular bleeding, and either of these tests should be closely monitored during resuscitation of the bleeding patient [48]. Plasma transfusion is indicated when the ratio exceeds 1.5 times the midrange normal value in these patients. Usually, an increase in factor levels of at least 10% will be needed for any significant change in coagulation status, so the usual dose is 3 to 4 units (approximately 10 to 15 mL per kg), but the amount will vary depending on the patient’s size and clotting factor levels (Table 89.2). Reversal of warfarin anticoagulation is indicated only if significant bleeding or risk of bleeding is present. Plasma may be used for this purpose, but, often, recurrent transfusion is required to maintain normal factor levels. Many patients receiving warfarin will not tolerate the volume of plasma required or require more rapid replacement for life-threatening bleeding in which case a prothrombin complex concentrate may be more appropriate.

</tr>
</tbody>
</table>

In a 70-kg patient:

| 1 Unit PLASMA increases most factors |
| ~2.5% |
| 4 Units PLASMA increase most factors |
| ~10% |

Plasma is indicated in the treatment of TTP, most commonly in conjunction with plasmapheresis. Many other disorders are treated by plasmapheresis, but, usually, plasma replacement is not used. Plasma should not be used for volume expansion unless the patient also has a significant coagulopathy and is bleeding.

**Cryoprecipitate**

Cryoprecipitate is prepared from plasma and contains fibrinogen, von Willebrand factor, factor VIII, factor XIII, and fibronectin. Cryoprecipitate is supplied in bags (each made from 1 whole blood unit) from multiple donors that have been resuspended in saline or plasma and pooled prior to transfusion. It must be kept at room temperature. The concentration of fibrinogen in cryoprecipitate units is up to 10 times that in plasma, and, therefore, blood levels can be increased rapidly with much smaller volumes.

Fibrinogen levels can drop rapidly in DIC, and is usually associated with other coagulation abnormalities that may in combination be treated with plasma. Isolated hypofibrinogenemia is infrequently associated with bleeding in adults, and correction should be reserved for patients with
clinical bleeding or patients who are a risk of bleeding as a result of imminent invasive procedures or trauma [26] with significant hypofibrinogenemia (<100 mg per dL).

Cryoprecipitate should not be used for patients with von Willebrand disease or hemophilia A (factor VIII deficiency) unless they do not (or are not known to) respond to DDAVP, and recombinant and/or virally inactivated preparations are not available. It is usually given for factor XIII deficiency, when virus-inactivated concentrates of this protein are not available. Cryoprecipitate is sometimes useful if platelet dysfunction associated with renal failure does not respond to dialysis or DDAVP and in other platelet function defects [79].

The amount of fibrinogen per bag of cryoprecipitate can vary widely between blood centers and depending on the donor’s fibrinogen concentration. The approximate fibrinogen increment with each bag of cryoprecipitate transfused can be calculated by the formula: 25 mg per plasma volume (in liters). Six bags will increase the fibrinogen level of a 70-kg patient approximately 45 mg per dL. To replace factor VIII or von Willebrand factor when specific factor concentrates are unavailable, the usual dose is 1 bag per 10 kg of body weight. Approximately 150 units of factor VIII and von Willebrand factor are provided per bag. Although single units of cryoprecipitate can be used in the preparation of locally applied fibrin glue for surgery, commercially available, virally inactivated concentrates have a higher fibrinogen concentration and are preferred for this purpose. A patient may donate autologous plasma for processing into cryoprecipitate prior to a planned surgical procedure.

Human fibrinogen concentrate (RiaSTAP) is a heat-treated, lyophilized fibrinogen (coagulation factor I) powder made from pooled human plasma. It is indicated for bleeding or procedure prophylaxis in patients with congenital hypofibrinogenemia or dysfibrinogenemia.
COMPLICATIONS OF TRANSFUSION

Transfusion-Related Risks

Infectious Complications

Because the recognition that human immunodeficiency virus (HIV) could be transmitted by blood transfusion in the mid-1980s, exclusion of donors with high risk has done more to decrease transfusion transmitted infection than any testing that has been implemented since that time [80]. Enzyme-linked immunosorbent assay testing for anti-HIV antibody was instituted in 1985 dropping the risk of HIV transmitted infection to 1 in 667,000 units [81]. The addition of P24 antigen decreased the window period between infection and detection to approximately 16 days [82], and polymerase chain reaction screening for HIV has decreased the current estimated risks/unit to as low as 1 in 2,000,000 [83].

As of early 2014, testing for infectious disease screening is performed for the following agents: HIV-1, HIV-2, human T-lymphotropic virus (HTLV)-I, HTLV-II, hepatitis C virus, hepatitis B virus, West Nile virus, *Treponema pallidum* (syphilis), and *Treponema cruzi*. In addition to these tests, platelet units are tested for bacterial contamination. Current risk estimates per unit for hepatitis B virus, hepatitis C virus, and HTLV are 1:1 million, 1:1.2 million, and 1:2.7 million, respectively [84].

CMV is a DNA virus acquired as a primary infection with body secretions, blood products, or organ allografts. Infection in a normal host usually is asymptomatic, but remains latent for life and can cause recurrent infection when it reactivates. CMV infection and seropositivity is extremely common, being 40% in highly industrialized areas, and is close to 100% in warmer climates, densely populated areas, and developing countries [85]. Transfusion-associated CMV infection in the immunocompetent patient with a normal immune system is usually asymptomatic, occurring 4 to 12 weeks after blood component exposure in 0.9% to 17% of patients [86]. In CMV negative, immunosuppressed neonates, transplant, and HIV-positive patients, the risk of CMV infection and severe end-organ disease and organ allograft rejection is high [87]. Leukocyte depletion of blood is similar to CMV seronegative blood in preventing CMV infection through transfusion [88].

Bacterial contamination of RBC and platelet units may occur during collection. RBC units may be contaminated with cold-loving organisms, such as Yersinia. Platelets are stored at room temperature, and multiple organisms can grow in those conditions. Although *Staphylococcus* and *Streptococcus* are the most frequently implicated, gram-negative
organisms have also been identified [89]. The incidence of bacterial contamination of platelets has been estimated to be as high as 0.1% [90]. The institution of bacterial testing of platelets in 2004 in the United States is expected to decrease this risk [91], and septic transfusion reactions are estimated to occur in less than 1:50,000 transfusions, but these are likely underreported. Symptoms of hypotension, fever, and chills almost always occur within 3 hours of the transfusion and may be complicated by severe shock and DIC [92]. Both the patient and the blood component bag should be cultured if bacterial contamination is suspected.

Other organisms that can be transmitted by blood transfusion include other hepatitis viruses, malaria and, rarely, syphilis. *T. cruzi*, the parasite responsible for Chagas disease is becoming a commonly transfusion transmitted disease in Central and South America, and has been reported in some Southern US states. Fear of transfusion transmission of new variant Creutzfeldt–Jakob disease has led to stringent criteria on blood donor eligibility and institution of universal leukoreduction in some European countries, but the risk of infection by transfusion is low [93] and testing is not universal.

In 2014, pathogen inactivation of platelets and plasma has been approved in the United States and has been used in some European countries since 2003. Units are photochemically treated using a psoralen compound and exposure to long-wavelength ultraviolet light to inactivate viruses, bacteria, protozoa, and leukocytes. Another inactivation process is sometimes used in Europe utilizing riboflavin and ultraviolet light.

Transfusion Reactions

A transfusion should be stopped immediately whenever a transfusion reaction is suspected. An **acute hemolytic transfusion reaction** (AHTR) occurs following transfusion of an incompatible blood component. Most are caused by naturally occurring antibodies in the ABO antigen system, but AHTR may occur with incompatibility of Rh, Kell, Kidd, Lewis, and other RBC antigen systems. The vast majority of cases are caused by failure of appropriate systems to identify the correct transfusion recipient [94]. Signs and symptoms include fever, hypotension, tachycardia, dyspnea, chest or back pain, flushing, and severe anxiety. Release of cytokines, such as tumor necrosis factor, interleukin 8, and monocyte chemoattractant protein-1 [95], is followed by fever, capillary leak, and activation of the hemostatic mechanism. If the reaction is severe, it may go on to cause a consumptive coagulopathy (DIC) and renal failure as a result of shock and deposition of thrombi in arterioles. Hemoglobinuria may be the first sign of hemolysis in the sedated patient. Centrifuging a
tube of blood and examining the plasma for a reddish discoloration can quickly make the diagnosis. Treatment should first of all be immediate discontinuation of the transfusion as soon as AHTR is suspected and then maintenance of venous access and fluid resuscitation if necessary. Pressor support may be necessary along with central venous pressure monitoring. AHTR is rare, estimated at 1:77,000 units [96].

**Delayed hemolytic transfusion reactions** (DHTRs) usually occur in patients who have been previously sensitized to an antigen through transfusion or pregnancy. A fall in titer over time may make incompatibility undetectable. A subsequent transfusion causes recall of the antibody, followed by a falling hematocrit 5 to 10 days later. The hematocrit will continue to fall until all of the incompatible transfused cells have been destroyed. DHTR can result in symptomatic or asymptomatic hemolysis, but has only rarely been reported to cause severe morbidity or mortality [97]. Once recognized, the patient is usually easily supported by transfusion of compatible RBCs.

**Febrile nonhemolytic transfusion reaction** (FNHTR) is a 1°C rise in temperature or greater that cannot be explained by the patient’s clinical condition. FNHTR usually occurs within 1 hour of completion of the transfusion. Reactions are more common with platelet transfusions and for patients who have been heavily transfused, and can be quite severe. FNHTR is often caused by sensitization to antigens on donor leukocytes [98]. Cytokines, released from the white cells during storage of cellular blood components, also appear to play a role [99]. Prestorage leukocyte depletion of RBCs and platelets by filtration may be helpful in patients for whom this is a problem. Leukocyte-reduced single-donor apheresis platelets are a possible alternative to leukocyte depletion by filtration of pooled random donor platelets. Occasionally, patients with persistent febrile reactions will require removal of most of the plasma (volume reduction) from platelet preparations. Apheresis platelets prepared with platelet additive solutions (PASs) may also decrease their occurrence. FNHTR should be differentiated from bacterial contamination, which is usually associated with higher fevers and other symptoms of sepsis. Antipyretics can be used to prevent or treat FNHTR. Some clinicians feel meperidine may be useful in the treatment of rigors, although this has not been shown to be beneficial in clinical trials.

**Transfusion-related acute lung injury** (TRALI) can be indistinguishable from adult respiratory distress syndrome [100,101], involving severe bilateral pulmonary edema and hypoxemia. Symptoms of dyspnea, hypotension, and fever typically begin 30 minutes to 6 hours
after transfusion, and the chest X-ray shows diffuse nonspecific infiltrates. Ventilatory support may be required for several days before resolution, but approximately 80% of patients improve within 48 to 96 hours. TRALI occurs when donor plasma contains an antibody, usually against the patient’s HLA or leukocyte-specific antigens. Lipids generated during prior storage of the transfused product and preexisting lung damage also appear to play parts in the pathogenesis of TRALI. Less often, the patient may have antibodies against donor leukocytes in the component. The blood center should be notified promptly so that components from the donor can be quarantined and the donor tested for antibodies against the patient.

**Transfusion-associated cardiovascular overload** may occur in patients sensitive to increased amounts of intravascular volume with transfusion and may initially present a clinical picture similar to TRALI. Unlike TRALI, diuresis is usually effective treatment.

**Allergic and anaphylactic reactions** are common and usually because of preformed immunoglobin E antibodies to specific proteins in the donor’s plasma. Mild urticaria complicates up to 3% of plasma infusions [102] and can be avoided with future transfusions by pretreatment with antihistamines and, in severe cases, with corticosteroids. Only in cases of severe reactions (anaphylaxis), washing of RBCs and platelets to remove all plasma is indicated. Slowing of the rate of transfusion and centrifugation to remove some of the plasma in a platelet component or the use of PAS will sometimes be effective in preventing future reactions among patients for whom this is a recurrent problem.

**Transfusion-related GVHD** (TRGVHD) is caused by infusion of donor lymphocytes that engraft and then proliferate in response to stimulation by foreign (host) antigens. TRGVHD typically begins 2 to 50 days after transfusion with rash, diarrhea, signs of hepatic inflammation, and pancytopenia [103]. TRGVHD occurs in patients with severe defects of cellular immunity, most notably hematopoietic stem cell transplantation patients, neonates, and patients with lymphoproliferative disorders. Transfusion from relatives and HLA-compatible donors is at risk of causing GVHD. It can be prevented by γ irradiation of cellular blood components.

### Immune Modulation

Transfusions have been known to induce immune tolerance following the observation made more than 20 years ago that multiply transfused kidney transplant recipients had an increased graft survival rate [104]. Transfusion-induced immunosuppression has been implicated in postoperative infection, increased cancer recurrence rates, and
development of non-Hodgkin lymphoma [105,106]. There is also evidence from animal studies that transfusion increases the risk of metastatic disease, although data in humans are inconclusive. Removal of donor leukocytes has been shown to decrease the immunomodulatory effects of blood transfusions. The clinical usefulness is clear only for prevention of alloimmunization in patients undergoing chemotherapy for acute myelocytic leukemia [50]. A prospective randomized study in patients undergoing cardiac surgery showed a decrease in infection rates when leukocyte reduced blood components were used [107]. This has led some centers to adopt policies of universal leukoreduction, but this remains controversial.

Table 89.3 summarizes some of the most important recent advances in transfusion medicine based on randomized controlled trials or meta-analyses of such trials.

Anemia in the Critical Care Setting

MARC S. ZUMBERG • MARC J. KAHN • ALICE D. MA

GENERAL PRINCIPLES

Anemia is common in the critical care setting. Up to 60% of patients are anemic upon admission to an intensive care unit (ICU) with a first hemoglobin concentration <9 g per dL [1,2]. Anemia will develop in nearly all patients at some point during the course of a prolonged ICU stay, and as a result, the majority of patients admitted more than 7 days receive a red blood cell (RBC) transfusion [1,3]. Anemia in the critically ill patient has been shown to be associated with poor outcomes; however, many interventions including red cell transfusion, erythropoietin (EPO), and iron supplementation have not been shown to consistently improve these same outcomes [2–4].

Certain anemias may be encountered more frequently in patients who are admitted to critical care units than in other settings, including anemias arising from iatrogenic sources (e.g., mechanical hemolysis caused by ventricular assist devices or intraaortic balloon pumps); those producing hemodynamic or systemic compromise that leads to a requirement for critical care (e.g., massive blood loss due to trauma, gastrointestinal lesions, or surgical invasion; thrombotic microangiopathies); and those arising in the context of prolonged critical illness (e.g., anemia of chronic disease/inflammation [ACD]). Losses from an enhanced frequency of phlebotomy for diagnostic testing in the critical care unit may contribute to the development or maintenance of anemia and has been estimated to account for 1 to 2 units lost during a typical hospital stay [4–6]. It has been reported that there is an additional 18% risk for development of moderate to severe hospital-
acquired anemia for every 50 mL of phlebotomized blood [7].

This chapter provides an overview of the evaluation and laboratory testing for anemia, with a focus on diagnoses that are the most clinically concerning, are important to recognize quickly, and are the most likely to be encountered in the critical care setting. Accordingly, the hemolytic anemias, including the microangiopathic hemolytic anemias, autoimmune hemolytic anemia (AIHA), and sickle cell syndromes, will be covered in more detail (Table 90.1). The ACD often develops in patients in the ICU and will also be a focus of this chapter. Anemia due to massive blood loss including trauma and gastrointestinal bleeding is essential to recognize, obtain proper consultation for, and treat appropriately, but the diagnosis is usually self-evident and will be covered in other areas of this textbook (Chapters 37 and 203).

Initial Evaluation

The etiologies of anemia in the critical care setting are diverse, but the evaluation of anemia in a critically ill patient initially should be approached in a manner similar to the noncritical care setting.

The patient’s volume status should be considered first, as an increase in the plasma volume may lead to a decrease in the measured hemoglobin or hematocrit that does not represent a true decrease in the red cell mass or oxygen carrying capacity. This situation is known as dilutional or spurious anemia and is particularly common in ICU patients who have been in positive fluid balance. Dilutional anemia does not require treatment, other than correcting the underlying deficit.

To more accurately develop a differential diagnosis, it should be determined whether the anemia predated the patient’s critical illness, developed in conjunction with the critical illness, or developed during the ICU stay (Table 90.2).

- Drug-induced hemolytic anemia
- Anemia of chronic disease/inflammation
- DIC

DIC, disseminated intravascular coagulation; TTP, thrombotic thrombocytopenic purpura.

**Laboratory Studies**

Anemias can be classified by the size of the RBCs as reflected by the mean corpuscular volume (MCV): microcytic (MCV, <80 fL), normocytic (80 to 100 fL), and macrocytic (>100 fL). A finite number of diagnoses constitute each of these categories, allowing the practitioner to narrow the differential diagnosis (Table 90.3). One should take caution to review the MCV prior to the transfusion of RBCs, as transfused donor RBCs may increase or decrease the MCV depending on the pretransfusion value.

Megaloblastic anemia
B₁₂ deficiency
Folic acid deficiency
Drug induced
Hypothyroidism
Liver disease
Hemolytic anemia with reticulocytosis
Myelodysplastic syndrome or other primary bone marrow disorders

MCV, mean corpuscular volume.

Several additional tests may be helpful for the evaluation of anemia. The reticulocyte count, which is a measure of the bone marrow’s ability to produce new RBCs, should be the initial test performed. The reticulocyte count is typically elevated in hemolytic anemias, acute gastrointestinal bleeding, or after supplementation of a missing nutrient such as iron or vitamin B₁₂. The reticulocyte count is typically low in primary bone marrow disorders, nutritional deficiencies, the ACD, and any condition leading to the underproduction of or resistance to EPO (e.g., renal disease). If a hemolytic anemia is suspected (i.e., due to consistently hemolyzed blood specimens, characteristic findings on physical examination [see later], or refractoriness to erythrocyte transfusion), measurement of total and unfractionated bilirubin (elevated), lactate dehydrogenase (LDH) (elevated), and haptoglobin (decreased) may be useful, although the results are not specific to hemolysis and may show a similar pattern in patients with advanced liver disease.

A review of the blood smear will often help to narrow the differential
diagnosis and quickly identify anemias due to causes that require expeditious, specialized management (e.g., thrombotic microangiopathies). Examples of erythrocyte abnormalities with classic blood smear findings include schistocytes (Fig. 90.1), sickle cells (Fig. 90.2), bite cells (Fig. 90.3), or spherocytes (Fig. 90.4), and identification of these aberrant forms is critical in making the correct diagnosis (Table 90.4).

**Therapeutic Red Cell Transfusion**

Clinicians caring for patients in critical care settings are often confronted with the decision to transfuse RBCs even before results of laboratory testing or other evaluation have elucidated the cause of the anemia. Erythrocyte transfusion in this setting should be guided by hemodynamic considerations, rather than a finite transfusion trigger [8]. Because of the (albeit low) risk of transmission of infectious pathogens and the potential for transfusion reactions and immunomodulation, and in light of increasing evidence from randomized trials that anemia is well tolerated in individuals without cardiopulmonary compromise, more restrictive transfusion policies are becoming the standard of care [2,8–10]. Principles of transfusion are discussed in greater detail in Chapter 89.
Use of Erythropoiesis-Stimulating Agents

In multiple randomized clinical studies, use of erythropoiesis-stimulating agents (ESAs) in critically ill patients as compared with placebo or no intervention had no statistically significant effect on overall mortality, length of hospital stay, ICU stay, or duration of mechanical ventilation. A possible decrease in mortality among severe traumatic brain injury patients has been noted [2,11–15]. A meta-analysis has shown that use of ESAs reduced the odds of a patient receiving at least one transfusion and modestly decreased the mean number of units of blood transfused by 0.41 units [13]. The optimal dosing and schedule of EPO remain to be determined [13,16], and the benefits of concomitant supplemental intravenous iron, which may be considered when the serum ferritin drops below 100 to 200 ng per mL or iron saturation drops below 20% [2], still is debated. A meta-analysis of off-label use of ESAs in critically ill patients showed an increase in thrombotic vascular events, but not other adverse events or death [17]. Thus, at the present time, there remains insufficient evidence to recommend the routine use of ESAs in critically ill anemic patients [1,13].

Hematology Consultation

If the etiology of the anemia is not apparent despite the above evaluation or if treatment options remain uncertain, hematology consultation should be initiated. A bone marrow aspirate and biopsy may be useful if the diagnosis remains in question or if a primary bone marrow disorder is suspected because of unexplained abnormalities (morphologic or quantitative) in other blood cell lineages.
HEMOLYTIC ANEMIAS

The hemolytic anemias are characterized by a decreased red cell life span. The physiologic sequelae of these disorders, in addition to the ability of the hemolytic process to cause a decrease in hemoglobin and oxygen carrying capacity in a short period of time, may lead to a requirement for critical care. The patient with hemolysis may be very or only minimally symptomatic, depending on the rate of red cell destruction and the degree of compensation by the bone marrow, which produces young red cells (reticulocytes) in response to the decreased hemoglobin.

Overview of Laboratory Features

Pathologic features of hemolysis differ greatly depending on whether the red cell destruction is primarily intravascular or extravascular. Biochemical evidence for intravascular hemolysis includes elevated levels of LDH and unconjugated bilirubin and decreased levels of haptoglobin, which is cleared from the circulation after binding free hemoglobin. Hemoglobinuria results when free hemoglobin is filtered through the glomerulus and is released into the urine, imparting a reddish color. Some hemoglobin in the urine is taken up by tubular cells and is converted to hemosiderin. This can be detected by checking for intracellular iron in the urine by staining the urine with Prussian blue stain. Extravascular hemolysis may be evidenced by only a declining hemoglobin level, although cases of brisk destruction of red cells may show elevations in LDH and unconjugated bilirubin.

Increased red cell production is evidenced by an increase in the number of circulating reticulocytes, which are young red cells whose large size typically results in an elevated red cell MCV and red cell distribution width. Circulating nucleated red blood cells (NRBCs) may be seen in cases of brisk hemolysis. Morphologic evidence of red cell destruction may be evident on the blood smear (see following sections and Figs. 90.1 to 90.4).

Immune-Mediated Hemolysis

The pathophysiology of immune-mediated hemolysis involves antibodies binding to red cells, with or without the activation of complement, leading to red cell destruction. If the antibody on the red cell surface is immunoglobulin G (IgG), then red cell destruction is mediated via Fc receptors on macrophages within the reticuloendothelial (RE) system. Complete or partial phagocytosis occurs causing the red cells to take a
spherocytic shape as opposed to the normal, more pliable, biconcave disc shape.

Antibodies which lead to hemolysis can be divided into two categories: Warm and cold, referring to the temperature at which the antibody optimally reacts with the red cell. Warm antibodies react optimally with red cells at temperatures 37°C and typically do not agglutinate red cells [18]. Cold antibodies typically react best at temperatures less than 32°C, with maximal reactivity at 4°C and lead to red cell agglutination [19]. The hallmark of AIHA is a positive direct Coombs test, which will detect the presence of either IgG or C3 bound to red cells (Table 90.6).

| TABLE 90.6 Interpretation of the Coombs Test and Differential Diagnosis |
|-------------------------------------------------|------------------|
| IgG positive | IgG negative |
| C3 positive | WAIHA | Drug-induced hemolysis |
| Drug-induced hemolysis | CAD |
| PCH |
| C3 negative | WAIHA | WAIHA (rare) |

In performing this test, red cells from the patient are washed to remove nonspecific proteins and antibodies. Next, antibodies to human IgG, human C3, or both are added to the cells. If the patient’s red cells have either IgG or C3 attached to them, the red cells will agglutinate, indicating a positive test. The specificity of the antibody can be tested by testing the patient’s serum against panels of red cells that express different subsets of red cell antigens. CAD, cold agglutinin disease; IgG, immunoglobulin G; PCH, paroxysmal cold hemoglobinuria; WAIHA, warm autoimmune hemolytic anemia.

Warm Autoimmune Hemolytic Anemia

In warm autoimmune hemolytic anemia (WAIHA), IgG antibodies are directed against red cell surface membrane antigens [18]. Most commonly, these antibodies are directed against members of the Rh blood group, but the specificity of the pathogenic IgG antibodies is not always identified. The IgG antibodies coat the red cells and may or may
not fix complement (C₃). IgG-coated red cell membrane fragments are engulfed by macrophages in the RE system (usually the spleen) [18,20]. As the red cell loses surface area, it loses the ability to retain its biconcave disc shape. As the shape with the smallest surface area-to-volume ratio is a sphere, the red cell becomes progressively more spherocytic with each pass through the splenic circulation [18].

WAIHA can manifest as a primary disorder, or alternatively, it can be secondary to an underlying disorder, such as collagen vascular disease (e.g., lupus) or a lymphoproliferative disorder (e.g., lymphoma). Approximately 30% of patients with chronic lymphocytic leukemia have a positive Coombs test, although a much lower proportion develops hemolysis [21]. AIHA may be associated with immune thrombocytopenia, a condition called Evans syndrome. AIHA can also be provoked by infection or can be induced by various drugs. Causes of WAIHA are listed in Table 90.7.

CAD, cold agglutinin disease; WAIHA, warm autoimmune hemolytic anemia.

**Clinical Features.** Almost all patients present with worsening and often debilitating fatigue. Older patients, and those with rapid hemolysis and ensuing severe anemia, may present with evidence of organ compromise such as dyspnea, angina, or syncope and can suffer myocardial ischemia, hypotension, and/or renal failure. Physical findings can include pallor, jaundice, and splenomegaly. Laboratory findings include an increased reticulocyte count, increased bilirubin (total and
indirect), and increased LDH. The direct Coombs test should be positive (Table 90.6), and typically spherocytes, microspherocytes, NRBCs, and/or anisocytosis are seen on the blood smear.

Transfusion In Patients With Warm Autoimmune Hemolytic Anemia. If the patient has heart failure, angina, shock, or evidence of hypoperfusion to vital organs, or if compensatory erythrocytosis is absent or inadequate because of an underlying illness that suppresses the bone marrow, such as leukemia, prior chemotherapy, or renal failure, then red cell transfusion should be performed [18]. The anti-erythrocyte autoantibody itself can also be occasionally directed against red cell precursors in the marrow, leading to an inappropriately low reticulocyte count [18,22]. Any transfusion in patients with WAIHA needs to be coordinated closely with the blood bank or transfusion service. The offending antibody will frequently interfere with performing a crossmatch to identify compatible blood for transfusion. It is critical to obtain a thorough transfusion and pregnancy history to determine the likelihood of an underlying alloantibody which may be masked by the autoantibody; testing a red cell eluate may be helpful in this regard. Crossmatching can be done using low ionic strength solution which will minimize nonspecific interactions, allowing the stronger alloantibody interactions to appear. If time allows, phenotyping can be performed; such a maneuver may help to minimize the risk of a delayed hemolytic transfusion reaction (DHTR). If crossmatched units are not available, phenotypically matched red cells are preferred. If not available, due to time constraints or the patient’s condition, then ABO and Rh type-specific, noncrossmatched, or “least incompatible” units should be used. Each unit should be transfused slowly, while the patient’s clinical status is closely assessed for evidence of worsening hemolysis. The blood bank may require that samples of the patient’s blood be drawn soon after the transfusion begins to record any evidence of hemolysis. This is termed an in vivo crossmatch.

Treatment. After hemostatic instability has been addressed through transfusion of RBCs, the initial treatment of WAIHA consists of immunosuppression which, if successful, may attenuate antibody production and allow the patient’s RBCs to survive normally in the circulation. First-line therapy consists of glucocorticosteroids, either intravenously such as methylprednisolone or oral prednisone, typically at 1 to 2 mg per kg daily [19]. Intravenous immunoglobulin (IVIG) has also been used but is less effective than in immune thrombocytopenic purpura
If steroids are ineffective, or if relapse occurs, then alternative immunosuppression should be considered. Agents which have been reported to be useful in WAIHA include rituximab, cyclophosphamide, mycophenolate mofetil, and azathioprine. Splenectomy should also be considered as a reasonable second-line treatment option in eligible patients. As with all hemolytic anemias, the administration of folic acid 1 to 5 mg per day, at least as long as hemolysis is ongoing, is recommended. The reticulocyte count and complete blood cell count (CBC) should be followed closely to monitor the effectiveness of therapy. The amount of blood drawn may be minimized by using pediatric tubes or “bullet” tubes, if available.

Cold Agglutinin Disease

In cold agglutinin disease (CAD), immunoglobulin M (IgM) antibodies target red cell surface antigens, typically with specificity to either “I” or “i.” These IgM antibodies optimally bind to red cells at “cold” temperatures (typically <32°C and most strongly at 4°C), and, given their ability to bind more than one RBC simultaneously, lead to the agglutination and clumping of RBCs in the distal microvasculature. IgM anti-erythrocyte antibodies fix complement to the red cell, leading to either intravascular or extravascular hemolysis. CAD may be primary or secondary due to lymphoproliferative disorders or infection.

Clinical Features. In most patients, CAD is a chronic condition characterized by mild to moderate hemolysis and episodic cyanosis and ischemia of the ears, tip of the nose, and digits. When episodic, cold-induced hemolytic episodes occur, intravascular hemolysis may be associated with shock, rigors, back pain, and renal failure.

Laboratory Evaluation. Cold agglutinin titers can be measured. On Coombs testing, complement (C3) is typically positive whereas IgG is negative, reflecting the underlying IgM autoantibody which more efficiently fixes complement (Table 90.6). The thermal amplitude of the autoantibody, not the antibody titer, however, best determines the severity of clinical symptoms. If binding occurs only at 4°C to 30°C, it is less clinically important than if significant binding occurs at temperatures more than 34°C, approximating more physiologic conditions. In fact, many normal individuals will have cold agglutinins detected at 4°C but have no clinical symptoms.

Treatment. In patients with chronic, mild CAD, the mainstay of treatment is avoidance of cold temperatures. Corticosteroids and splenectomy are typically less effective in CAD as compared with WAIHA.
Other agents, such as chlorambucil, cyclophosphamide, and rituximab, have been used successfully [19,29]. In patients who present with impending or actual end-organ damage such as myocardial ischemia or stroke, plasmapheresis may be effective because IgM remains primarily intravascular and can be efficiently removed. Plasmapheresis may need to be performed preoperatively in surgeries requiring cardiopulmonary bypass or cardioplegia [19,30]. In all patients, care must be taken to keep the extracorporeal tubing warm and to warm intravenous fluids and blood products, or hemolysis may worsen. Folic acid repletion is recommended in all patients.

Paroxysmal Cold Hemoglobinuria

IgG is the pathogenic antibody in this rare condition. Similar to IgM antibodies in CAD, the IgG antibody in paroxysmal cold hemoglobinuria (PCH) binds to red cells only at cold temperatures where it fixes complement. Unlike the antibody in CAD, however, it is activated at warmer temperatures and does not agglutinate red cells. This antibody is called the Donath–Landsteiner antibody and is directed against the “P” red cell antigen [19]. Red cell destruction occurs primarily via activation of the complement cascade and leads to subsequent intravascular hemolysis. In the past, PCH was primarily a disease associated with tertiary syphilis and, therefore, has become much less common in the penicillin era. Currently, PCH is primarily a pediatric disorder (often following a viral infection), only rarely affecting adults. Patients suffer episodic, cold-induced hemolysis. There is no cold-induced digital ischemia.

The diagnosis is made by detection of the Donath–Landsteiner antibody. The Coombs test is typically negative for IgG and positive for C3 (Table 90.6). The blood bank should be alerted to the possibility of this diagnosis, as special considerations are required for detection. Serum is collected from the patient and kept at 37°C. Patient serum and normal red cells are next chilled to 4°C, then warmed to 37°C. The presence of lysis is revealed by the detection of free hemoglobin in the sample. Controls must be performed where red cells and serum are incubated at 37°C and in a separate test tube at 4°C. In both of these scenarios, there should be no lysis detected [31], as a positive test requires the extremes of temperature.

Drug-Induced Hemolytic Anemias

More than 130 drugs have been reported to cause immune-mediated hemolytic anemia [32]. Drugs can induce hemolytic anemia by three general mechanisms: the innocent bystander mechanism, hapten
mechanism, and a true autoimmune mechanism [33,34]. These are described in Table 90.8. It should be noted that many drugs may lead to a positive direct Coombs test in the absence of overt hemolysis. Thus, a positive direct Coombs test should not be inferred to represent hemolysis unless there is worsening anemia in conjunction with consistent laboratory evaluation. Currently, piperacillin is the most common drug to cause immune hemolytic anemia [35].

RBC, red blood cell; RE, reticuloendothelial.

Other drugs may cause hemolysis by alternative mechanisms. Oxidant agents such as dapsone and other sulfa drugs may cause hemolysis in a dose-dependent fashion, especially in individuals with glucose 6-phosphate dehydrogenase (G6PD) deficiency who are impaired in their ability to detoxify the oxidant damage to hemoglobin (see “Glucose 6-Phosphate Dehydrogenase Deficiency” section later in the chapter). Ribavirin, used to treat hepatitis C, causes hemolysis in a dose-dependent fashion. Its mechanism of red cell damage is unclear, but it may relate to nucleotide depletion. Other agents such as cyclosporine and tacrolimus may cause a microangiopathic hemolytic anemia due to endothelial...
damage (see “Microangiopathic Hemolytic Anemia” section).
MICROANGIOPATHIC HEMOLYTIC ANEMIA

The microangiopathic hemolytic anemias are a heterogeneous group of disorders defined by vascular damage leading to thrombosis of small arterioles and capillaries resulting in distortion and fragmentation of erythrocytes, hemolysis, subsequent anemia, and thrombocytopenia [36,37]. The hallmark finding on the blood smear is the schistocyte, a fragmented RBC (Fig. 90.1). It is essential that the intensivist recognize the differential diagnosis of microangiopathic hemolytic anemia as many of the diagnoses require prompt recognition and treatment (Table 90.9) [36]. If the underlying etiology of a microangiopathic hemolytic anemia is in question, immediate hematology consultation is strongly recommended to evaluate for life-threatening diagnosis such as thrombotic thrombocytopenic purpura (TTP).

Clopidogrel
Chemotherapeutic agents such as mitomycin C, gemcitabine, and VEGF inhibitors

HELLP, hemolysis, elevated liver enzymes, low platelets; TTP, thrombotic thrombocytopenic purpura; VEGF, vascular endothelial growth factor.

TTP, once almost uniformly fatal, can now be treated effectively in the majority of patients with prompt recognition and initiation of therapeutic plasma exchange (TPE) [36]. The diagnosis should be suspected in any patient who presents with unexplained microangiopathic hemolytic anemia and thrombocytopenia [36,38–40]. The “classic pentad” of microangiopathic hemolytic anemia, thrombocytopenia, mental status changes, renal failure, and fever is present in fewer than 25% of patients at presentation. Only unexplained microangiopathic hemolytic anemia and thrombocytopenia are required to begin TPE; the aforementioned clinical sequela are likely late manifestations of the disease [36,39–41].

Moake and others first noted unusually large von Willebrand factor (vWF) multimers in the plasma of affected patients and proposed them to be central in the pathophysiology of the disorder [42]. In the late 1990s, two groups reported that a vWF-cleaving protease (later termed ADAMTS-13, as a member of a disintegrin and metalloproteinase with thrombospondin components family of proteins) was found to be absent in familial TTP and inhibited by an antibody in the majority of cases of acquired TTP [43,44]. The absence of ADAMTS-13 was subsequently shown to prevent the breakdown and lead to the accumulation of ultra large molecular weight vWF multimers [42,45,46]. These ultra large vWF multimers efficiently bind to glycoprotein receptors on platelet surfaces leading to adhesion of platelets to the blood vessel endothelium and subsequently to small vessel occlusion affecting a variety of organs [36,42]. Hemolytic anemia occurs because of the mechanical shearing of RBCs as they transverse the turbulent and occluded microvasculature, thus leading to the classic findings of schistocytes seen on the peripheral blood smear (Fig. 90.1).

Clinical Manifestations
As discussed earlier, the clinical manifestations of TTP can be quite varied. Neurologic symptoms may range from subtle confusion to frank seizures or coma. Renal dysfunction may range from mild proteinuria or azotemia to acute renal failure. Occlusion in blood vessels of the cardiac conduction system may lead to arrhythmias and sudden cardiac death. Pancreatitis has been described and should be considered in patients with abdominal pain. Fever is often noted. Essentially any organ system may be affected leading to a wide range of symptoms.

**Laboratory Features**

Laboratory evaluation usually reveals a hemolytic anemia with at least (and often much more than) two schistocytes or greater than 1% of RBCs per 100 × field on microscopic examination (Table 90.4 and Fig. 90.1). Coagulation studies such as the activated partial thromboplastin time and the prothrombin time are typically normal, whereas they are usually prolonged in disseminated intravascular coagulation (DIC). The Coombs test is typically negative. Most cases of classic acquired TTP are associated with a severe deficiency of ADAMTS-13 (<5%), and an inhibitory antibody can be demonstrated [36,39–41]. ADAMTS-13 results are often not available in real time, are not required to make the diagnosis, and therefore not routinely used to make initial therapeutic decisions regarding the initiation of plasma exchange. ADAMTS-13 levels have prognostic value regarding the risk of relapse but are less useful in determining the likelihood of initial response to plasma exchange. Mild to moderate decreases in ADAMTS-13 are not specific and may be seen in a variety of disorders including sepsis [34,37,39,41].

Schistocytes may be seen in conditions other than TTP (Table 90.9). These conditions usually have in common damage to the blood vessel endothelium, leading to the release of ultra large vWF multimers. The presentation of these syndromes may mimic TTP. The hemolytic uremic syndrome (HUS) often presents with a primary component of renal failure [47]. Conditions other than TTP are not associated with severe (<5%) deficiency of ADAMTS-13 and TPE is typically much less or ineffective. When atypical HUS is suspected, TPE is often initiated until the ADAMTS-13 results become available [36,40,41].

The distinction between TTP and HUS may be difficult, although it has been reported that a serum creatinine >150 to 200 µmol per L or a platelet count >30 × 10⁹ per L is rarely associated with severe ADAMTS-13 deficiency as seen in TTP [41,47]. Classic childhood HUS is usually preceded by hemorrhagic diarrhea caused by *Escherichia coli* O157:H7. In atypical HUS, renal failure is more severe and extrarenal manifestations are less common or absent as compared to TTP [41,47]. ADAMTS-13 is not usually severely depressed in HUS, suggesting a
different pathophysiology between these two related conditions [36]. Atypical HUS has been linked to uncontrolled activation of the complement system due to either congenital or acquired mutations or antibodies against various factors in the complement pathway [36,48]. As the ability to differentiate between TTP and atypical HUS is often unclear, prompt TPE is often initiated in atypical HUS, even though efficacy is less as compared to TTP [36,41]. Eculizumab, a terminal complement inhibitor, was approved and has become the standard of care for the treatment of atypical HUS since 2011 [36,47,49]. As soon as the diagnosis is confirmed/deemed highly likely or if there is high suspicion and TPE is ineffective, eculizumab should be promptly initiated. Meningococcal vaccination is recommended prior to the first dose. Both nephrology and hematology consultation should be sought when the diagnosis of atypical HUS is suspected.

**Treatment**

TPE with fresh frozen plasma (FFP) at a 1.0 to 1.5 × plasma volume should be initiated as soon as idiopathic TTP is suspected [36–41]. A dual-lumen, large-bore, dialysis-type catheter is often needed for the procedure, despite the coexisting thrombocytopenia. With prompt TPE, 80% to 90% of patients with classic TTP survive this once uniformly fatal disease [36]. The effectiveness of TPE is thought to be due to both the removal of an anti-ADAMTS-13 antibody and the replacement of ADAMTS-13 in donor FFP. If TPE is not readily available, FFP should be infused at a rate of 30 mL/kg/d while arrangements for TPE are made [41]. Randomized trials have supported the efficacy of TPE over simple plasma infusion which is often problematic given the large volume of FFP required [36,39–41].

TPE should be continued until the platelet count and LDH have normalized for 2 days [36,39,41]. Plasma exchange is often tapered down to every other day upon remission, but this practice has not been critically studied and its efficacy in preventing relapse is uncertain [41]. In refractory or relapsing patients, cryosupernatant plasma, devoid of vWF, should be considered [38]. Catheter-related infections should also be investigated and have been documented to lead to relapse. Immunosuppressants such as glucocorticoids and cyclosporine as adjuncts to plasma exchange have been used, but efficacy remains uncertain [36,38–41]. Platelet transfusion is generally avoided, as it is thought to possibly exacerbate thrombosis, although evidence is conflicting [50,51].

Rituximab has been increasingly used as adjuvant therapy to TPE in both the initial and refractory settings [52]. Recent guidelines have stated that rituximab should be considered along with TPE and steroids during
an acute event and recommended in patients who have a refractory episode of TPE despite plasma exchange [52]. Recombinant ADAMTS-13 is under development and may prove to be effective in the future.

**Disseminated Intravascular Coagulation**

Although microangiopathic hemolytic anemia may be present in patients with DIC, typically the thrombotic or bleeding manifestations of DIC are more clinically significant. DIC, which is often due to an underlying serious or catastrophic event such as septicemia or an obstetric emergency, will be covered in greater detail in Chapter 94.

**Other Causes of Microangiopathic Hemolytic Anemia**

The differential diagnosis of microangiopathic hemolytic anemia includes other diagnoses listed in Table 90.9. Appropriate consultation and treatment should be pursued dependent on the most likely diagnosis.
HEMOGLOBINOPATHIES

Sickle Cell Anemia

Sickle cell anemia results from the presence of a point mutation leading to an amino acid substitution (valine for glutamic acid) in the sixth position of the beta chain of hemoglobin. An unstable form of hemoglobin (hemoglobin S) is produced which polymerizes in the setting of dehydration or hypoxia, leading to irreversible sickling of erythrocytes. Erythrocyte sickling is responsible for a variety of clinical conditions including extremely painful episodes in the back and extremities. Patients may be symptomatic if they are homozygous for hemoglobin S; if they are compound heterozygotes for hemoglobin S, hemoglobin C, hemoglobin D, and hemoglobin E; or if they also have concomitant \( \beta \)-thalassemia. The most common complications of sickling disorders leading to ICU admission are listed in Table 90.10.

Transfusion

Although patients with sickling disorders are nearly always anemic, routine transfusions are not indicated for hemodynamically stable
anemia, routine vasoocclusive crisis, routine pregnancies, or simple surgical procedures that do not require general anesthesia. In general, hematology consultation is indicated if transfusion is considered, as the need for transfusion usually suggests a more complicated clinical scenario. Transfusion therapy can be simple, chronic, or performed via RBC exchange. Simple transfusion involves infusion of a sufficient volume of red cells to improve tissue oxygenation. Chronic simple transfusions are primarily used to prevent stroke recurrence. RBC exchange, performed (where available) via erythrocytapheresis using a non-collapsible, large-bore, dialysis-type catheter, involves the removal of the patient’s hemoglobin S red cells, followed by replacement of RBCs from a non–hemoglobin S donor targeting a final hemoglobin no higher than 8 to 10 g per dL with hemoglobin S less than 30%. RBC exchange is often used in the management of acute stroke, severe acute chest syndrome (ACS), or multiorgan failure as a more rapid and efficient way to remove hemoglobin S and improve oxygen delivery. As opposed to simple transfusion, which can further increase iron load, exchange transfusion is also helpful in iron-overloaded patients because iron is removed with removal of hemoglobin S red cells. As an alternative to pheresis, manual exchange transfusion involves removing 500 mL of blood, followed by infusion of 300 mL normal saline, followed by another 500 mL removal of blood, and subsequent transfusion of 4 to 5 units of packed red cells. However if possible, automated exchange by pheresis is more effective at achieving targeted hemoglobin concentrations [53]. With both exchange modalities, care should be taken to keep the end hemoglobin value no higher than 10 g per dL to minimize the risk of hyperviscosity.

Alloimmunization, typically to the Rh (E, C), Kell (K), Duffy (Fya, Fyb), and Kidd (Jk) antigens, occurs in up to 30% of patients [54]. Alloimmunization can be minimized by transfusing red cells that have been phenotypically matched for these red cell antigens. If phenotypically matched units are not available, crossmatched red cell units that are negative for C, E, and Kell are recommended.

**Acute Chest Syndrome**

Pulmonary complications frequently cause significant morbidity and mortality in patients with sickling disorders and are a common reason for ICU admission. Among the pulmonary complications, the ACS is among the most frequently observed in the ICU setting.

**Clinical Features.** ACS can be defined by a constellation of fever, hypoxemia, chest pain, leukocytosis, and new pulmonary infiltrate in a patient with a sickling disorder [55]. Although most common in patients
homozygous for hemoglobin S, ACS can also be seen in decreasing frequency in patients with hemoglobin SC disease and S/β + thalassemia. Importantly, the clinical definition of ACS does not indicate a specific etiology. ACS can be caused by infection, thrombosis, fat embolism, or any combination of these conditions. A large multicenter study showed that a specific cause of ACS could be identified in more than 50% of patients studied [56]. The most common etiologies observed were fat embolism and infection. Specific etiologies of ACS from this study of 671 episodes are listed in Table 90.11.

ACS, acute chest syndrome.

**Physiologic Markers.** Secretory phospholipase A₂, a potent inflammatory mediator, has been implicated as a cause of lung damage in patients with ACS [57], and serum levels may be predictive of impending ACS [58]. In addition, circulating activated endothelial progenitor cells have been proposed as a potential etiology of ACS [59], as have levels of pentraxin 3, an acute phase reactant and key component of innate immunity [60].

**Treatment.** Treatment of ACS depends in part on the clinical presentation. If the sputum Gram stain suggests infection with a particular organism, targeted antibiotic therapy should be initiated without delay. Interestingly, although pneumococcus is a frequent cause
of infection in children with ACS, it is much less common in adults, in whom mycoplasma is more frequently implicated [55]. However, when an infectious etiology of ACS is suspected, empiric coverage for pneumococcus remains appropriate. In addition, because of the high mortality associated with ACS, empiric antibiotic coverage for mycoplasma and chlamydia should also be strongly considered. A recently published NIH expert panel report strongly recommends treatment of ACS with cephalosporins, a macrolide, and oxygen to maintain a saturation of greater than 95% [61]. Similarly, the use of incentive spirometry was strongly encouraged by this same expert panel. Maintaining hydration and oxygenation during episodes of ACS are imperative to prevent further sickling. However, fluids must be administered carefully to avoid fluid overload. There are no data to support the routine use of anticoagulants in ACS, and in the absence of data, this practice should be avoided.

Patients with ACS and hypoxia (PO\(_2\) <75 mm Hg) should be transfused red cells by either simple or exchange transfusion [61]. One small single-institution study found no difference between the two transfusion modalities [62]. The NIH expert panel recommends simple transfusion to a hemoglobin of 10 g per dL unless there is rapid progression of ACS as demonstrated by oxygen saturation below 90% despite supplemental oxygen, increasing respiratory distress, worsening chest X-ray, or decline in hemoglobin despite supplemental oxygen [61]. Because patients with hemoglobin SC disease typically have baseline hemoglobin levels in the 10 to 11 g per dL range, exchange transfusion is the preferred means of red cell administration. In addition to providing a source of oxygen delivery, exchange transfusion also decreases levels of inflammatory mediators such as soluble vascular cell adhesion molecule-1 [63].

**Acute Stroke**

Stroke is one of the most morbid complications of sickle cell disease, with a prevalence of more than 20% in some series [64]. In addition to overt stroke, more than 60% of patients with sickle cell disease have evidence of brain damage from occult infarction that is incidentally found on magnetic resonance imaging [65]. The pathophysiology of stroke in sickle cell patients is complicated. Stroke is related to nitric oxide depletion, hypercoagulability, and abnormalities of the major cerebral arteries. Unfortunately, stroke recurrence is common with more than 50% of cases occurring within 36 months following the initial event [66]. The presence
of constricted cerebral arteries with collateralization (moyamoya syndrome) is associated with recurrent stroke and may be alleviated by surgical vascular bypass [67]. Although transcranial Doppler measurement of blood velocity has predictive value for stroke in pediatric patients with sickle cell disease, the measurement of cranial blood flow velocity is less able to stratify the risk of stroke for adults [68].

**Treatment.** Although there have been no specific trials addressing the issue, antiplatelet agents can be used in the treatment of acute stroke in adults with sickle cell disease, similar to patients without sickle cell disease [69]. Even in the absence of large randomized studies, an NIH expert panel recommends exchange transfusion for sickle cell patients with confirmed acute stroke on neuroimaging studies [61]. In the setting of acute stroke, emergent red cell exchange transfusion to reduce hemoglobin S to less than 30% is recommended. Similarly, consensus opinion suggests that conventional angiography can be used in sickle cell patients suspected of having an aneurysmal subarachnoid hemorrhage [70]. Because of the osmotic dye load which might increase intracerebral sickling, experts also suggest exchange transfusion prior to angiography [71]. Acute retinal artery occlusion can be considered as an ophthalmic stroke. The exact pathophysiology of retinal artery occlusion in sickle cell disease and risk factors for the condition are not known [72]. Similarly, there are scant data on the treatment of retinal artery occlusion in sickle cell anemia. At this time, it is reasonable for sickle cell patients presenting with acute thrombotic stroke or acute retinal artery occlusion to undergo red cell exchange transfusion. In addition, antiplatelet agent administration appears reasonable.

**Acute Cholecystitis**

Patients with hemolytic disorders, including sickle cell disease, form gallstones composed of the insoluble salt, calcium bilirubinate. It is estimated that up to 75% of adults with sickle cell disease have ultrasound-identified gallstones [73]. An NIH expert panel recommends treating acute cholecystitis with antibiotics and surgical consultation (consensus opinion) [61]. This group also recommends a laparoscopic approach if surgery is indicated and recommends simple transfusion to a hemoglobin of 10 g per dL prior to surgery. This recommendation is based on a randomized trial that suggested that simple preoperative transfusion to a hemoglobin level of 10 g per dL is not associated with more complications than preoperative red cell exchange transfusion to a target hemoglobin S less than 30% [74]. In addition, simple transfusion is associated with a lower rate of alloantibody formation, as fewer units of RBCs are transfused. The use of postoperative incentive spirometry is
strongly encouraged because of a decreased incidence of ACS [75].

**Pulmonary Hypertension**

Pulmonary hypertension is a recently recognized cause of morbidity and mortality in sickle cell disease occurring in more than 30% of patients and conferring an increased death rate ratio of 10.1 [76]. Pulmonary hypertension may be secondary to nitric oxide scavenging by free hemoglobin released during hemolysis. Such scavenging can lead to the synthesis of vasoconstrictors such as vascular cell adhesion molecule 1 and E-selectin. Hemolysis also leads to the release of arginase from hemolyzed red cells, reducing nitric oxide synthesis. The formation of reactive oxygen and nitrogen species catalyzed by free hemoglobin may also lead to pulmonary vasoconstriction. Pulmonary hypertension, in conjunction with high cardiac output, is a major cause of congestive heart failure in patients with sickle cell disease.

The management of patients with sickle cell disease and pulmonary hypertension remains controversial. Some authors have noted a decreased incidence of pulmonary hypertension in retrospective studies of patients treated with hydroxyurea [77], but this finding is not universal. A small study found that therapy with sildenafil improved exercise capacity in patients with sickle cell disease and pulmonary hypertension [78]. However, a recent trial using sildenafil in children with sickle cell disease and pulmonary hypertension was prematurely suspended because of an increased incidence of adverse events including painful crisis. Speculation exists that endothelin antagonists, such as bosentan, may also be effective in reducing pulmonary pressures, although prospective trials are lacking. Similar is also the case for epoprostenol and oral arginine [79].

Currently, there is insufficient evidence in the medical literature to suggest specific treatment strategies for patients with sickle cell disease and pulmonary hypertension. At a minimum, conservative management including oxygen therapy to treat hypoxia and echocardiographic documentation and aggressive treatment of right heart failure are recommended [61].

**Hyperhemolysis**

Patients with hyperhemolysis, characterized by a lower posttransfusion hemoglobin compared with the pretransfusion value, present with profound anemia and hemolysis despite red cell transfusion support [80]. The pathophysiology of hyperhemolysis in sickle cell disease remains unclear but may be related to a combination of bystander hemolysis, suppression of erythropoiesis, and destruction of RBCs due to contact
lysis via activated macrophages [81]. There are case reports supporting the use of IVIG or corticosteroids in addition to plasma to red cell exchange transfusion to maintain enough RBCs to support the circulation [82]. EPO administration may also be of benefit in cases where the reticulocyte count is inadequate. Rituximab has been reported as an effective treatment for this condition [83]. Although hyperhemolysis can recur, typically it occurs as an isolated event. Prompt recognition is important to avoid life-threatening anemia in the setting of continued erythrocyte transfusion.

Aplastic Crisis

Aplastic crisis in sickle cell disease is usually secondary to either folic acid deficiency or infection with parvovirus B19. Aplasia secondary to folic acid deficiency is more common in late pregnancy when folic acid requirements are increased. Infection with parvovirus can be accompanied by marked marrow necrosis [84]. Treatment of parvovirus infection–induced aplasia in immunocompetent individuals is supportive using red cell transfusion to restore the hemoglobin to a safe level and resolves upon clearance of the virus.

Sepsis

Because patients with sickling disorders are functionally asplenic, infection remains a common reason for hospitalization. Pneumonia is the most common infection and may be caused by pneumococcal species, especially if the patient did not receive appropriate immunizations. Treatment of the patient with sickle cell disease and sepsis parallels the treatment of similar patients without a coexistent hemoglobinopathy. Broad-spectrum antibiotics which can later be tailored to the most likely organism should be administered immediately. Adequate hydration must be maintained during an infectious episode to prevent further sickling of erythrocytes. Organisms responsible for sepsis in the sickle cell population can be found in Table 90.12. Consideration of immunization status is important when considering the most likely organism.

| TABLE 90.12 | Organisms Responsible for Blood-Borne Infections in Patients with Sickling Disorders |

### Iron Overload

Because patients with sickle cell disease are transfused throughout their lifetime, these patients run the risk of iron overload. The liver, heart, and pancreas are particularly vulnerable to the effects of excess iron. Iron chelation is particularly important in iron-overloaded patients (serum ferritin $> 1,000$ ng per mL or liver iron concentrations of greater than 2.2 mg iron per g dry weight of liver tissue). Oral iron chelators including deferasirox or deferiprone have increased tolerability as compared with parenteral deferoxamine and appear as effective at removing iron [85].

### Thalassemia

Patients with thalassemia can develop high output heart failure that can lead to ICU admissions. Treatment of heart failure in thalassemic patients is similar to the management of heart failure in other patient populations including the use of diuretics, angiotensin-converting enzyme inhibitors, and β-blockers. Chelation therapy with deferasirox is recommended in patients with thalassemia major and iron overload, especially if iron overload has caused cardiac toxicity. Transfusion support is required in symptomatic anemia. Unless a coexistent
hemoglobinopathy is present, stroke, ACS, and other common complications of sickle cell disease are not typically seen.

**Hemolytic Transfusion Reactions**

Patients may experience hemolytic transfusion reactions that are either immediate (acute) or delayed. Acute hemolytic transfusion reactions (AHTRs) typically manifest with a feeling of impending doom. Subsequently, back pain, hypotension, red urine, and shock develop. Renal failure due to the massive hemoglobin load may occur, and DIC often ensues. Between 1990 and 1992, the majority of the 150 preventable transfusion-related fatalities reported to the Food and Drug Administration (FDA) were due to ABO-incompatible RBC transfusions leading to an AHTR [86–88]. Indeed, AHTR is typically the result of human error, in specimen collection, labeling, or transfusion [87]. Errors within the laboratory are much less common. Although this dramatic presentation is classic, it is important to note that a rise in temperature of 1°C above baseline may be the sole initial presentation of a hemolytic transfusion reaction and necessitates the cessation of transfusion of that unit of red cells and initiation of workup for transfusion reaction. In the case of an immediate hemolytic transfusion reaction, hemoglobinuria and hemoglobinemia may be seen, and reaction between the remnant of the transfused unit and the patient’s pretransfusion serum can be identified. Treatment consists of stopping the transfusion as soon as the reaction is suspected and maintenance of blood pressure with fluids and pressors as needed.

DHTRs typically present 1 to 4 weeks after transfusion of a unit of red cells. The patient may present with fatigue, jaundice, pallor, or red- or tea-colored urine. Patients with sickling disorders may come to medical attention because of a new or worsening pain crisis. The hemoglobin will be lower than that seen posttransfusion. The LDH and bilirubin will be increased, the reticulocyte count will likely be elevated, and the antibody screen will be positive, and a new alloantibody often identified. The DHTR is typically due to mismatches of non-ABO red cell antigens. Patients should be issued a card stating the antigen to which they have made a new alloantibody and told to present this card prior to all future transfusions. This is especially important in cases of antibodies to the Kidd antigen, as these alloantibodies are typically transient and may not be detectable on future antibody screens.

**Glucose 6-Phosphate Dehydrogenase Deficiency**

G6PD deficiency, a sex-linked trait primarily affecting men most commonly of African American or Mediterranean descent, is the most common erythrocyte enzyme defect in the world [89]. G6PD is necessary
to maintain glutathione in its reduced state in the erythrocyte. Patients deficient in this enzyme are subject to oxidative hemolysis when exposed to certain drugs and toxins, or during episodes of infection. A sample list of drugs to be avoided in G6PD-deficient patients is provided in Table 90.13. Because acute infection makes oxidative hemolysis more likely, there has been confusion about the safety of certain drugs in G6PD-deficient patients. A list of drugs that can be safely administered to G6PD-deficient patients is shown in Table 90.14. A more exhaustive drug list can be found at many Web sites dedicated to G6PD deficiency (e.g., www.g6pd.org). G6PD deficiency is seldom a major issue in critically ill patients because the anemia is typically not severe, and the patients are closely monitored. However, in solid organ transplant recipients who are exposed to oxidant drugs such as trimethoprim–sulfamethoxazole or dapsone, the diagnosis should be strongly considered in the setting of a new hemolytic or unexplained acute anemia [90].

In the more common African American variant of G6PD, enzyme levels are elevated in young reticulocytes, and therefore measurement of this enzyme should not be attempted in the setting of an acute hemolytic episode, where the majority of circulating red cells are young.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired disease in which an abnormal stem cell clone gives rise to red cells, white cells, and platelets that lack proteins which are normally attached to the cell surface by a glycosylphosphatidylinositol (GPI) anchor. Among these proteins are CD55 and CD59, which are responsible for inactivating complement on the surface of red cells. PNH cells are therefore more susceptible to complement-mediated lysis [91]. Patients with PNH may come to the attention of the intensivist with complications such as hemolysis, pancytopenia, arterial, or venous thrombosis (including the Budd–Chiari syndrome/hepatic vein thrombosis). Patients may also develop pancytopenia due to marrow hypoplasia, as there is an association with primary bone marrow disorders such as aplastic anemia, myelodysplastic
syndrome (MDS), and acute myelogenous leukemia [92,93].

Flow cytometry showing the absence of GPI-linked surface molecules CD55 and CD59 on erythrocytes and granulocytes has supplanted older testing (such as the Ham’s test) for the diagnosis of PNH [93]. Eculizumab has been FDA approved for the treatment of hemolysis due to PNH. Patients treated with eculizumab show markedly lower rates of hemolysis and also thrombosis [94–98] but are at increased risk of infection with meningococcus, requiring immunization prior to use [93].

**Hereditary Spherocytosis**

Hereditary spherocytosis (HS) is an autosomal dominant disorder of red cell membrane skeletal proteins leading to a lack of anchoring of the red cell lipid bilayer to its skeletal backbone [99–101], leading to a characteristic spherocytic shape. Patients have lifelong hemolysis which is often well compensated. However, with even mild infections, the hemolysis can accelerate, and the patient can become more anemic. Splenomegaly is present in many patients and splenic rupture may occur after trauma. Patients with HS may present with an aplastic crisis manifested by severe reticulocytopenia and anemia often due to parvovirus B-19 infection which transiently suppresses the bone marrow’s ability to produce red cells and compensate for the accelerated hemolysis [101,102]. The Coombs test will be negative and should be used to differentiate HS from WAIHA, which can present similarly. Diagnosis is made by showing an increase in osmotic fragility and a decrease in eosin-5’-maleimide binding to band 3 [103]. RBC transfusion may be administered to patients with aplastic crisis.

**Hemolysis from Infectious Agents**

Certain infectious pathogens cause hemolysis that can be severe or life threatening. Malaria is prototypic; infection with falciparum malaria is known as blackwater fever, due to the massive hemolysis caused by this agent. *Babesia microti* is another intracellular parasite that can lead to hemolysis. It is carried by the same tick as Lyme disease and can look like malarial forms on peripheral smear. *Bartonella bacilliformis*, the agent responsible for Oroya fever, and *Verruca peruviana*, an extracellular parasite, can lyse red cells leading to dramatic hemolysis. In endemic regions of the world, these organisms are leading causes of hemolysis in critically ill patients. The toxin of *Clostridium welchii*, an agent of gas gangrene, may cause severe hemolysis. The bacterium produces a lysolecithinase, which attacks the red cell membrane bilayer. *Clostridium perfringens*, another agent causing gas gangrene, also leads to hemolysis via the action of phospholipases produced in its exotoxin [104]. In certain cases, the hemolysis can be severe enough to produce a disparity between
the hemoglobin and the hematocrit. This infectious complication typically follows bowel or gynecologic surgery.

Hemolysis Associated with Chemical and Physical Agents

Arsenic, especially arsine gas, can lead to hemolysis, as it can elevate levels of copper in the blood. Wilson’s disease, which is a disorder of copper metabolism, may present with hemolysis as part of its clinical picture [105]. Some dialysis centers have had difficulty with copper contamination of their water supply, leading to severe hemolysis [106]. Insect and spider bites, especially the bite of the brown recluse spider (Loxosceles reclusa), can lead to hemolysis, as can certain snakebites [107]. Severe burns can lead to hemolysis, as the red cell membrane is sensitive to temperatures more than 55°C.

Other Causes of Anemia in the Critical Care Setting

Iron deficiency leads to a hypoproliferative anemia due to the inability to synthesize hemoglobin. Iron deficiency may be caused by chronic blood loss, decreased iron intake (either from dietary reasons or from iron malabsorption as occurs in celiac sprue or following gastrointestinal bypass), or both. In the ICU, red cell transfusion is the most immediate way to correct the anemia, but in patients with low hemoglobin but without hemodynamic compromise, oral or intravenous iron is preferred. Parenteral iron may be preferred in iron-deficient patients who have undergone gastrointestinal bypass, those with inflammatory bowel disease, cancer patients, those who suffer from functional iron deficiency, patients undergoing treatment with EPO, or patients with chronic kidney disease [108–111]. Iron dextran, iron sucrose, iron gluconate, ferumoxytol, and iron carboxymaltose are all available for intravenous use. The newer formulations of iron dextran have a lower rate of severe allergic reactions compared with older dextran preparations, but the incidence continues to remain higher than with the newer non-dextran iron preparations [112–119]. Ferumoxytol is not approved for inpatient use and has recently been given a black box warning to avoid use in anyone with a history of prior allergic reaction to ANY other iron preparation. The iron deficit can be calculated by the following formula: (desired hemoglobin – actual hemoglobin) × (weight in pounds) + storage iron. Storage iron is estimated at 1,000 g for men and 600 mg for women.
Megaloblastic Anemia

Megaloblastic anemia is a rare cause of anemia in the ICU but should be suspected in individuals presenting with a macrocytic, hypoproliferative anemia (high MCV, low reticulocyte count) (Table 90.5). Vitamin B₁₂ and folic acid levels should be measured, but accuracy may be affected in the acute setting. The measurement of homocysteine and methylmalonic acid (MMA) is a more sensitive way to assess for these nutritional deficiencies but can also be altered in the critically ill patient [120]. Typically, both homocysteine and MMA are elevated in B₁₂ deficiency, although homocysteine alone is elevated in folic acid deficiency. Elevation of homocysteine and MMA may be the first laboratory signs of subclinical B₁₂ deficiency. The peripheral smear may show oval macrocytes and hypersegmented neutrophils. Other anemias which are hypoproliferative and macrocytic include the MDSs, aplastic anemia, the anemia of hypothyroidism, and liver disease (Table 90.5). Additionally, medications such as hydroxyurea, methotrexate, and zidovudine may lead to macrocytosis.

Anemia of Chronic Disease (ACD)/Inflammation

The ACD/inflammation is common in the ICU and its etiology is multifactorial (Table 90.15) [121]. Once thought to occur over weeks to months, the ACD has been shown to occur in less than a week and is thus thought to be a major contributor to anemia in critically ill patients [121,122]. Several studies have shown elevated levels of pro-inflammatory mediators such as tumor necrosis factor-alpha; interleukin-6; C-reactive protein; and interferons-α, -β, and -γ in ACD [121,123,124]. This acute-phase reactant response has been shown to inhibit EPO production, blunt the erythropoietic response, and play a central role in iron metabolism, leading to the sequestration of iron. Iron metabolism is primarily mediated by the antimicrobial peptide hepcidin, which impairs the ability to export iron from gut epithelial cells and hepatocytes into the bloodstream [125]. Hepcidin is upregulated in the ACD, leading to the sequestration of iron. In the ACD, the serum iron (Fe), total iron-binding capacity (TIBC), and percentage iron saturation (iron/TIBC) are typically low. Ferritin, an acute-phase reactant, is often normal or elevated, as opposed to iron deficiency where it is low. Renal failure is common in the ICU and also may contribute to the ACD, especially when progressive [121,126]. Increased red cell destruction has also been noted in the ACD because of decreased RBC deformability [121].

TABLE 90.15 Mechanisms of the Anemia of...
Chronic Disease/Critical Illness

Blood loss
  Phlebotomy
  Active bleeding
Decreased red cell production
  Decreased production of EPO
  Blunted response to EPO
  Sequestration of iron through upregulation of hepcidin
Renal dysfunction
Increased red cell destruction
  Reduced red blood cell deformability

EPO, erythropoietin.
CONCLUSIONS

As demonstrated in this chapter, anemia is exceedingly common in the critical care setting, but its etiology remains diverse. A rational approach to the evaluation of anemia includes review of the white blood count, platelet count, MCV, reticulocyte count, peripheral blood smear, and any prior CBCs that may be available. If hemolysis is suspected, LDH, bilirubin, and haptoglobin will provide additional information to support or refute this diagnosis. A Coombs test is often sent if the etiology of hemolysis remains in question. As highlighted in the chapter, certain causes of anemia such as blood loss, microangiopathic hemolytic anemia, complications of sickle cell disease, hemolysis from drugs as well as foreign devices, and ACD are frequently present in critically ill patients and should be considered in the ICU patient population. Specific treatment recommendations are based on the underlying diagnosis. Minimizing the volume and frequency of blood draws is essential. Conservative transfusion thresholds are increasingly being used in the absence of hemodynamic compromise or acute blood loss. The role of ESAs has been investigated but remains uncertain. If the etiology of the anemia remains obscure, or the management of an underlying diagnosis remains uncertain, hematology consultation is recommended.

Thrombocytopenia is common in the intensive care unit (ICU) with platelet counts below $50 \times 10^9$ per L occurring in 12% to 13% of ICU patients and below $10 \times 10^9$ per L in 2% to 3% [1–3]. A variety of disease processes can lead to thrombocytopenia, ranging from an epiphenomenon of the illness that led to the ICU admission to a devastating complication of therapy. The differential diagnosis of thrombocytopenia is very broad. Table 91.1 lists some causes of special interest to the intensivist.

| Disseminated intravascular coagulation |
| Drug-induced thrombocytopenia |
| HELLP syndrome |
| Hemophagocytic syndrome |
| Heparin-induced thrombocytopenia |
| Liver disease |
| Posttransfusion purpura |
| Pseudothrombocytopenia |
| Thrombotic thrombocytopenia purpura |

HELLP, Hemolysis, Elevated Liver tests, and Low Platelets.

The immediate priorities in thrombocytopenic patients are to establish the validity and severity of the thrombocytopenia, evaluate for life-threatening processes such as heparin-induced thrombocytopenia (HIT)
or thrombotic thrombocytopenic purpura (TTP), and initiate therapy. In the critical care setting, therapeutic decisions often have to be made before a definitive cause of the thrombocytopenia is established.

**INITIAL EVALUATION**

The initial assessment should be rapid, focusing on whether the patient is bleeding or experiencing thrombosis; the underlying disorder(s) leading to the ICU admission; current medications; and (if available) past medical history.

In the assessment of bleeding, one should distinguish whether the patient is suffering from “structural” aberrancies (e.g., bleeding from a gastric ulcer) or generalized bleeding, which may suggest a hemostatic defect such as may occur due to thrombocytopenia. One should inspect sites of instrumentation such as intravenous (IV) sites or chest tube drainage, and the mucosa for bleeding. The fingertips and toes should be examined for evidence of emboli or ischemia.

Exposure to medication is a common cause of thrombocytopenia. One should carefully review the record of current and recently administered medications and ask the patient (if possible) and family about medications (prescribed, over the counter, and “natural” [4]) that the patient has recently taken.

**Laboratory Testing**

In thrombocytopenic patients, examination of the blood smear can quickly reveal whether pseudothrombocytopenia (artifactual platelet clumping) is present and verify the degree of thrombocytopenia. Although exceptions do exist, the magnitude of thrombocytopenia can be an aid in the differential diagnosis of low platelet counts (Table 91.2). HIT and thrombotic microangiopathy (including TTP) often present with modest thrombocytopenia (50 to 100 × 10⁹ per L). The smear should be carefully reviewed for the presence of fragmented red cells (schistocytes). Laboratory assessment of liver function and renal function also should be assessed. A markedly elevated level of lactate dehydrogenase (LDH) level out of proportion to other liver function abnormalities characteristically occurs in TTP and Hantavirus infection. If there is any suspicion of HIT, all heparin should be stopped and alternative antithrombotic agents should be started. Assessment of platelet function can be difficult and must be based largely on clinical judgment. The bleeding time or the platelet function assay are rarely useful in the evaluation of a thrombocytopenic patient, because the low platelet count lead to prolongations in the test end point.
### TABLE 91.2 Typical Platelet Counts in Various Disease States

**Moderate thrombocytopenia (50–100 × 10⁹/L)**
- Disseminated intravascular coagulation
- Hemophagocytic syndrome
- Heparin-induced thrombocytopenia
- Thrombotic thrombocytopenic purpura

**Severe thrombocytopenia (<20 × 10⁹/L)**
- Drug-induced thrombocytopenia
- Immune thrombocytopenia
- Posttransfusion purpura

### Diagnostic Clues

The reason for the ICU admission is an important step in evaluation of thrombocytopenia [5] (Table 91.3). For example, thrombocytopenia in patients who present with sudden-onset multiorgan system failure may indicate TTP or sepsis. In long-term critical care patients, new-onset thrombocytopenia may be a manifestation of HIT, drug-induced thrombocytopenia, occult or established sepsis, or bacteremia [6].

IMMEDIATE THERAPY—PLATELET TRANSFUSION

Although platelet thresholds below which critically ill patients are at risk of severe bleeding are likely to vary among patients, clinical practice generally dictates that a platelet count above $10 \times 10^9$ per L does not require platelet transfusion; as long as the patient is stable without signs of bleeding, is not receiving platelet inhibitors, has preserved renal function, does not require an invasive procedure, and does not have aggressive disseminated intravascular coagulation (DIC) [7]. If any of these are present, especially major or life-threatening hemorrhage (such as intracranial), then a threshold of greater than $50 \times 10^9$ per L is reasonable. An exception is thrombocytopenia caused by thrombotic microangiopathy (TTP), wherein platelet transfusion is contraindicated [8]. Platelet transfusions should comprise six platelet concentrates or one single-donor plateletpheresis unit. Additional discussion regarding transfusion of blood products in critically ill patients is found in Chapter 89.
CAUSES OF THROMBOCYTOPENIA

Heparin-Induced Thrombocytopenia

HIT occurs because of the formation of antibodies directed against the complex of heparin and platelet factor 4 [9]. This complex in a minority of cases binds to the Fcγ RIIA receptor, activating platelets and macrophages leading to a procoagulant state. The frequency of HIT is 1% to 5% when unfractionated heparin is used but less than 1% with low molecular-weight heparin [10]. HIT is more common in women and in postsurgical patients [11].

HIT should be suspected when there is a sudden onset of thrombocytopenia with either at least a 50% drop in the platelet count from baseline or the platelet count falling to less than 100 × 10⁹ per L in a patient receiving heparin in any form. HIT usually occurs at least 4 days after starting heparin but may occur suddenly in patients with recent (less than 3 months) exposure [12]. An often overlooked feature of HIT is recurrent thrombosis in a patient receiving heparin despite a normal platelet count [13]. Another clinical clue is a biphasic pattern of thrombocytopenia following cardiac surgery; recovery from the postsurgical thrombocytopenia followed by recurrent thrombocytopenia is strongly predictive of HIT [14]. A scoring system (the four Ts) has been validated in several studies as a means of assessing the pretest probability of HIT [15] (Table 91.4). Patients with scores of 0 to 3 are very unlikely to have HIT and can forego PF4-heparin antibody testing and empiric therapy.

The diagnosis of HIT can be challenging in the critical care patient who has multiple reasons for being thrombocytopenic. In this situation, the laboratory assay for HIT is helpful. Two levels of HIT testing exist. A widely available ELISA assay that detects the presumed pathogenic anti-heparin-platelet factor 4 antibodies is evaluated initially [16]. This test is very sensitive but in some populations not specific. For example, 10% to 50% of cardiac surgery, dialysis, or ICU patients will show positive results. The value of testing is that a negative test rules out HIT in all but the highest risk patients.

A second type of test is a functional platelet aggregation assay that consists of patient plasma, donor platelets, and heparin. If added heparin induces platelet aggregation, the test is considered to be positive. The test is technically demanding; but, if performed carefully, can be sensitive and specific [16]. Because of substantial frequency of false positivity of PF4-heparin ELISA, a positive test should be confirmed by a functional assay, even if treatment for HIT already has been initiated.

The first step in therapy of HIT consists of stopping all heparin. Low-molecular-weight heparins cross-react with the HIT antibodies, and therefore these agents are also contraindicated. Institution of warfarin therapy alone following a diagnosis of HIT has been associated with an increased risk of thromboses and is also contraindicated. Because of the high risk of thrombosis (53% in one study) [10] among HIT patients, antithrombotic therapy should be administered to all patients [17]. For immediate therapy of HIT patients, several antithrombotic agents are available [18] (Table 91.5).

</table>

\(^a\) aPTT, activated partial thromboplastin time; CABG,
coronary artery bypass grafting; HIT, heparin-induced thrombocytopenia.

Fondaparinux is not approved for treatment of HIT. Its use, however, may be considered after initial anticoagulation with a direct thrombin inhibitor has been administered and the platelet count has recovered, while awaiting a therapeutic INR from therapy with warfarin [18].

Argatroban is a direct thrombin inhibitor with a short half-life of 40 to 50 minutes. Dosing is $2 \mu g/kg/min$ with the infusion adjusted to keep the activated partial thromboplastin time (aPTT) 1.5 to 3 times normal. One advantage of argatroban is that it is not renally excreted, so no dose adjustment is necessary in renal disease [19]. These characteristics make it the most useful agent for patients in the critical care unit. However, argatroban must be used with caution in patients with severe liver disease by using an initial dose of $0.5 \mu g/kg/min$ [20]. Also, metabolism appears to be decreased in patients with multiorgan system failure and these patients should receive a dose of $\mu g/kg/min$ [21]. Argatroban (like all thrombin inhibitors) prolongs the prothrombin time/international normalized ratio (PT/INR) making initiation of warfarin therapy difficult. Options for converting a patient from argatroban to warfarin include:

1. Use the chromogenic Xa assay to adjust warfarin therapy aiming for a factor X level of 15% to 25%.
2. If the dose of argatroban is $2 \mu g/kg/min$ or less, one can simply aim for a PT/INR of more than 4.0 as therapeutic.
3. When platelets recover, change the patient to fondaparinux and initiate warfarin.
4. When platelets recover, change the patient to a direct oral anticoagulant.

Bivalirudin is a semisynthetic direct thrombin inhibitor that has been tested mostly in the setting of cardiac disease. This agent is an option for patients with HIT who need cardiac procedures and is especially an option for cardiac bypass with the most common dose being a 1 mg per kg bolus and infusion at 1.75 to 2.5 mg/kg/h to keep the activated clotting time $> 300$ seconds [22].

The indirect anti-Xa inhibitor fondaparinux does not cross-react with HIT antibodies suggesting a potential role in therapy of HIT [23]. However, it has not been studied as extensively in HIT as there are rare reports of a syndrome similar to delayed-onset HIT [24]. In addition, its long half-life of 19 hours and renal clearance do not make it practical to
use in most ICU patients.

Theoretically, direct oral anticoagulants may be an option, but there are no substantial data on their use in acute HIT [25]. They are best used in patients with a history of HIT or for long-term anticoagulation when the platelet count has returned to normal.

The issue of platelet transfusion remains controversial [26]. Patients with HIT rarely bleed, which reduces clinical concern over the potential for platelet transfusions; but a prudent approach is to reserve transfusion of platelets for the rare patient with severe thrombocytopenia who also has life-threatening bleeding.

As mentioned above, initiation of warfarin as the sole antithrombotic agent in the initial treatment of HIT has been associated with limb gangrene. In patients to be started on warfarin, it should be started in small doses (2 to 5 mg daily) once the platelet count has recovered. These often malnourished patients tend to have a dramatic response to warfarin therapy, and excessive anticoagulation can easily occur. One should overlap warfarin and parental therapy by 2 to 3 days, as there is evidence that patients may do worse if therapy with a direct thrombin inhibitor is truncated [20].

Patients with HIT should be carefully screened for any thrombosis, at least by performing lower extremity Doppler ultrasound. If thrombosis is present, a minimum of 3 months of therapeutic anticoagulation is required, whereas HIT without thrombosis usually is treated with 30 days of therapeutic anticoagulation.

Thrombotic Thrombocytopenic Purpura

TTP should be suspected when any patient presents with thrombocytopenia and microangiopathic hemolytic anemia, as evidenced by schistocytes on the blood smear and biochemical evidence of hemolysis; end-organ damage, manifesting as renal insufficiency or neurologic phenomena; and fever. Patients with TTP may not present with all of the aforementioned features. Critical care patients with TTP often present with intractable seizures, strokes, or sequela of renal insufficiency. Postsurgical TTP may occur 1 to 2 weeks after major surgery, and is heralded by decreasing platelet counts and renal insufficiency [27]. Many patients who present to the critical care unit with TTP have been misdiagnosed as having sepsis, “lupus flare,” or vasculitis.

The majority of patients with the classic form of TTP have an inhibitor
against an enzyme that is responsible for cleaving newly synthesized von Willebrand factor (VWF) [28]. VWF is synthesized as an ultra large multimer that can spontaneously aggregate platelets. The enzyme, ADAMTS13, cleaves VWF into a smaller form that can circulate without spontaneously binding platelets [29]. Presumably in TTP, when ADAMTS13 is inhibited, the ultra large multimers spontaneously aggregate platelets leading to the clinical syndrome of TTP. However, some patients with classic TTP have normal activity of ADAMTS13, implying other factors are important in pathogenesis of the disease.

There is currently no single diagnostic test for TTP; rather, the diagnosis is based on the clinical presentation [30]. Patients uniformly will have a microangiopathic hemolytic anemia with the presence of schistocytes on the peripheral smear. Renal insufficiency without severe renal failure is the most common renal manifestation. Thrombocytopenia may range from a mild decrease in platelet number to platelets being undetectable. The finding of thrombocytopenia with a relative normal PT helps eliminate DIC from the differential [31]. The LDH is often very elevated and is a prognostic factor in TTP. Finding very low levels of ADAMTS13 (<10%) is specific to TTP; but, as testing can take time and the test is not sensitive, initiation of therapy should not depend on assay results.

Untreated TTP is rapidly fatal. Mortality in the pre-plasma exchange era ranged from 95% to 100%. Plasma exchange therapy is presently the cornerstone of TTP treatment and has reduced mortality to less than 20% [32].

Glucocorticoid therapy, either 1 to 2 mg per kg of methylprednisolone until remission or 1 gm of methylprednisolone initially, may be given to patients who have TTP [33,34]. Glucocorticoids may be continued until the patient has fully recovered or longer, given the presumed autoimmune nature of the disease and the high relapse rates. Plasma infusion is beneficial, but plasma exchange has been shown to be superior to simple plasma infusion in therapy of TTP [35]. This may be due to the ability of plasma exchange to give large volumes of fresh frozen plasma and removal of inhibitory antibodies. In patients in whom plasma exchange is not readily available, plasma infusions should be started at a dose of 1 unit every 4 hours. Patients with all but the mildest cases of TTP should receive 1 to 1.5 plasma volume exchange each day for at least 5 days (see Chapter 96). Daily plasma exchange should be continued daily until the LDH has normalized, at which point the frequency of exchange may be tapered, starting with every other day exchange. If the platelet count falls or LDH level rises, daily exchange should be reinstated. Although the platelet count can be affected by a variety of external influences, the LDH level tends to be the most reliable marker of disease activity. There is evidence that the use of anti-CD20 therapy may reduce
the incidence of relapses and shorten the duration of therapy in refractory disease [36]. In patients with refractory TTP, aggressive measures such as twice a day exchanges, splenectomy, or immunosuppression need to be considered [37].

**Hemolytic Uremic Syndrome**

Classically, hemolytic uremic syndrome (HUS) comprises the triad of renal failure, microangiopathic anemia, and thrombocytopenia. Two major forms are recognized: a “typical” form, which occurs in young children with an antecedent illness, and an “atypical” form, which is increasingly being recognized as a disease of complement activation [33].

**Typical HUS**

Typical HUS occurs when HUS occurs after a prodrome of bloody diarrhea [38]. Most often, etiology is infection with *Escherichia coli* O157:H7 but increasingly other serotypes such as O26 and O104:H4 are being reported. Patients come to medical attention either because of the diarrhea or because of symptoms of renal failure. In HUS, thrombocytopenia can be mild in the $50 \times 10^9$ per L range. Extrarenal involvement is common in typical HUS. Neurologic involvement can be seen in 40% of patients with seizure being the predominant feature. Elevated liver function tests are seen in 40% of patients and 10% of patients have pancreatitis. Patients with classic HUS respond to conservative therapy and renal replacement therapy. Treatment of severe cases or those with prominent extrarenal manifestations is controversial, as studies suggest no benefit with plasma exchange [39]. Although benefit in atypical HUS, data currently suggest no role for eculizumab in typical HUS. Most patients recover some renal function, though some patients have long-term renal damage.

**Atypical HUS**

Atypical HUS is associated with excess complement activation that leads to renal damage with resultant renal failure [40]. Some patients may transiently respond to plasma exchange, but then relapse with relentless decline in renal function. Atypical HUS may recur following renal transplant. Proof of the role of complement activation is the dramatic response seen in patients with complement inhibitor treatment. Atypical HUS is a clinical diagnosis and should be considered in the patient with HUS that has no preceding diarrheal syndrome or in the patient with suspected TTP who has normal ADAMTS13 levels and prominent renal
disease. Patients with atypical HUS should receive therapy with the C5a inhibitor eculizumab, as this has consistent and long-term clinical benefits in atypical HUS [41]. Patients receiving this agent should be vaccinated for meningococcal infections as the risk of these infections is increased with blockade of the terminal part of complement.

**Therapy-Related Thrombotic Microangiopathies**

Thrombotic microangiopathies (TM) syndromes can complicate a variety of therapies [42]. TMs can be associated with medications such as cyclosporine, tacrolimus, gemcitabine, and thienopyridines. Cyclosporine/tacrolimus-associated TM occurs within days after the agent is started manifesting as a falling platelet count, falling hematocrit, and rising serum LDH level. Some cases have been fatal, but often the TM resolves with decreasing the dose of the calcineurin inhibitor or changing to another agent.

In the past TM, was most commonly seen with the antineoplastic agent mitomycin C, with a frequency of 10% when a dose of more than 60 mg was used [43]. Presently, the most common antineoplastic drug causing TM is gemcitabine with an incidence of 0.1% to 1% [44]. The appearance of the TM syndrome associated with gemcitabine can be delayed, and the condition can be fatal. Severe hypertension often precedes the clinical appearance of TM [45]. The use of plasma exchange is controversial [46], and there are reports of the use of the complement inhibitor eculizumab halting TM [47]. The increasing use of vascular endothelial growth factor inhibitors such as bevacizumab and sunitinib has been associated with TM syndromes as well [48].

TM has been reported with other drugs including the thienopyridines: ticlopidine, clopidogrel, and prasugrel. The frequency of ticlopidine-associated TM may be as high as 1:1600; and, as this drug is often prescribed for the patient with vascular disease, the patient may be initially misdiagnosed as having recurrent strokes or angina [49]. The frequency of TTP using clopidogrel and prasugrel is low at 0.0001%; but, as they are widely prescribed, it is the second most common cause of drug-induced TM [50]. Almost all cases of clopidogrel-induced TTP occur within 2 weeks of starting the drug. All patients with thienopyridine-associated TM should receive plasma exchange.

TMs can complicate both autologous and allogeneic stem cell transplants [51]. The incidence ranges from 15% for allogeneic to 5% for autologous stem cell transplants. Several types of TMs are recognized in
stem cell transplantations [51,52]. One is “multiorgan fulminant” which occurs early (20 to 60 days posttransplant), has multiorgan system involvement, and is often fatal. Another type of TM is similar to calcineurin inhibitor TM. A “conditioning” TM, which occurs 6 months or more after total body irradiation, is associated with primary renal involvement. Finally, patients with systemic cytomegalovirus (CMV) infections can present with a TM syndrome related to vascular infection with CMV. The etiology of bone marrow transplant–related TM appears to be different from that of “classic” TTP, as autoantibodies to ADAMTS13 have not been found in stem cell transplant TM–related vascular damage [53]. The therapy of stem cell transplant TM is uncertain. Patients should have their calcineurin inhibitors doses decreased. The response to plasma exchange is poor with fulminant or conditioning-related TM.

Pregnancy-Related Thrombocytopenic Syndromes

One should consider three syndromes in the critically ill pregnant woman who presents with thrombocytopenia. These are the HELLP syndrome, fatty liver of pregnancy, and TTP (Table 91.6) [54,55].

HELLP, Hemolysis, Elevated Liver tests, and Low Platelets; TTP/HUS, thrombotic thrombocytopenic purpura/hemolytic uremia syndrome; AFLP, acute fatty liver of pregnancy; LDH, lactate dehydrogenase.

The acronym HELLP syndrome (Hemolysis, Elevated Liver tests, Low Platelets) describes a variant of preeclampsia [56]. Classically, HELLP
syndrome occurs after 28 weeks of gestation in the patient with preeclampsia but can occur as early as 22 weeks in patients with the antiphospholipid antibody syndrome [57]. The preeclampsia need not be severe. The first sign of HELLP is a decrease in the platelet count followed by abnormal liver function tests. Signs of hemolysis are present with abundant schistocytes on the smear and a high LDH. HELLP can progress to liver failure, and deaths are also reported due to hepatic rupture. Unlike TTP, fetal involvement is present in the HELLP syndrome with fetal thrombocytopenia reported in 30% of cases. In severe cases, elevated D-dimers consistent with DIC are also found. Delivery of the child will often result in cessation of the HELLP syndrome, but refractory cases require dexamethasone (most commonly dosed as 10 mg every 12 hours) and, rarely, plasma exchange [58]. About a quarter of women who suffer from HELLP will have a recurrence with a later pregnancy.

Fatty liver of pregnancy also occurs late in pregnancy and is only associated with preeclampsia in 50% of cases [55,59]. Patients present with nonspecific symptoms of nausea and vomiting, but can progress to fulminant liver failure. Patients develop thrombocytopenia early in the course; but, in later stage, can develop DIC and very low fibrinogen levels. Mortality rates without therapy can be as high as 90%. Hypoglycemia, low antithrombin, and high ammonia levels can help distinguish fatty liver from other pregnancy complications [59]. Treatment consists of prompt delivery of the child and aggressive blood product support.

TTP can occur anytime during pregnancy often leading to diagnostic confusion because of the overlap of symptoms between TTP and HELLP syndrome [60]. A unique presentation of TTP occurs in the second trimester at 20 to 22 weeks [61]. The fetus is uninvolved with no evidence of infarction or thrombocytopenia, if the mother survives. The pregnancy appears to promote TTP, as TTP will resolve with termination of the pregnancy and can recur with the next pregnancy [62]. Therapy includes termination of pregnancy or supporting the patient with plasma exchange until the fetus is viable. Pregnancy-related TTP is a common presentation of congenital TTP; and, if ADAMTS13 inhibitors are not found, the patients should undergo genetic testing. An unusual complication of pregnancy is a HUS-type syndrome seen up to 28 weeks postpartum. This form of HUS is severe, and permanent renal failure often results despite aggressive therapy. Many of these patients have defects in regulatory proteins of complement such as factor H deficiency. This may explain the severity of their renal failure [63].

Disseminated Intravascular Coagulation

At the most basic level, DIC is the clinical manifestation of inappropriate
thrombin activation [64]. Inappropriate thrombin activation can be caused by sepsis or obstetric disasters. The activation of thrombin leads to (1) conversion of fibrinogenic to fibrin, (2) activation of platelets (and their consumption), (3) activation of factors V and VIII, (4) activation of protein C (and degradation of factors Va and VIIIa), (5) activation of endothelial cells, and (6) activation of fibrinolysis.

The clinical manifestations of DIC depend on the balance of thrombin activations and secondary fibrinolysis balanced by the ability of the patient to compensate for the DIC. Patients with DIC can present in one of four patterns:

1. Asymptomatic. Patients can present with laboratory evidence of DIC but no bleeding or thrombosis. This is often seen in patients with sepsis or cancer. With further progression of the underlying disease, these patients can rapidly become symptomatic.

2. Bleeding. The bleeding is caused by a combination of factor depletion, platelet dysfunction, thrombocytopenia, and excessive fibrinolysis. These patients may present with diffuse bleeding from multiple sites such as IV sites, areas of instrumentation, and surgical wounds.

3. Thrombosis. Despite the general activation of the coagulation process, thrombosis is unusual with acute DIC. Exceptions include cancer patients, trauma patients, and certain obstetric patients. Most often the thrombosis is venous, but arterial thrombosis and nonbacterial thrombotic endocarditis have been reported [65].

4. Purpura fulminans. This severe form of DIC is described in more detail later.

The most effective way to treat DIC is to treat the underlying cause that is driving thrombin generation [66]. In the past, there was concern about replacement of depleted blood cells and coagulation proteins in DIC because of fears of “feeding the fire.” This has not been well validated, and replacement is mandatory, if depletion occurs and bleeding ensues. Measurement of laboratory tests that will reflect the basic parameters essential for both blood volume and hemostasis is helpful. Replacement therapy is based on the results of these laboratories and the clinical situation of the patient (Table 91.7). Additional discussion regarding transfusion of blood products in critically ill patients is found in Chapter 116.
## TABLE 91.7 Management of DIC: Transfusion

### The five basic tests of hemostasis\(^a\)

</tbody>
</table>

### Guidelines for transfusion in patients at high risk of bleeding\(^b\)

- **A.** Platelets <50 \(\times\) 10\(^9\)/L: give platelet concentrates or 1 unit of single-donor platelets.
- **B.** Fibrinogen < 150/dL: give 10 units of cryoprecipitate\(^c\)
- **C.** Hematocrit below 30%: give red cells
- **D.** Protime > twofold the upper limit of normal and aPTT abnormal: give 2–4 units of FFP\(^d\)

---

\(^a\)These laboratory tests should be repeated after administering blood products serially. A record of the test and the blood products administered should be maintained.

\(^b\)Patients with DIC who are not actively bleeding generally do not require replacement of platelets or coagulation factors, unless an invasive procedure is planned or other circumstances are present; see text.

\(^c\)For a fibrinogen level less than 150 mg/dL, transfusion of 10 units of cryoprecipitate is expected to increase the plasma fibrinogen level by 100 mg/dL.

\(^d\)In patients with DIC and a markedly prolonged PT and aPTT, one can give 2–4 units of fresh frozen plasma (FFP) initially.

Heparin therapy is reserved for the patient who has thrombosis as a component of their DIC. Given the coagulopathy that is often present, specific heparin levels instead of the aPTT are monitored to guide anticoagulation therapy.
**Purpura Fulminans**

DIC in association with necrosis of the skin may occur in two situations [67]. Primary purpura fulminans is most often seen following a viral infection [68]. In this case, the purpura fulminans starts with a painful red area on the lower extremities that rapidly progresses to a black ischemic lesion. Acquired deficiency of protein S may be present [69]. Secondary purpura fulminans is most often associated with meningococcemia infections, but it can occur in any patient with overwhelming infection [70]. Post-splenectomy sepsis syndrome patients and those with functional hyposplenism due to chronic liver diseases are also at risk [71]. Patients present with signs of sepsis, and the skin lesions often involve the extremities and may lead to amputation. As opposed to primary purpura fulminans, those with secondary purpura fulminans will have symmetrical ischemic lesions at the distal parts of the body (toes and fingers) that ascend as the process progresses. Adrenal infarction (Waterhouse–Friderichsen syndrome) can occur which leads to severe hypotension [72].

Therapy for purpura fulminans is controversial. Primary purpura fulminans, especially cases with post-varicella autoimmune protein S deficiency, may respond to plasma infusion titrated to keep the protein S level more than 25% [67]. Intravenous immune globulin has also been reported to help decrease the anti-protein S antibodies. Heparin has been reported to control the DIC and the extent of necrosis. The starting dose in these patients is 5 to 8 units/kg/h [73]. Critically ill patients with secondary purpura fulminans have been treated with plasma drips, plasmapheresis, and continuous plasma ultrafiltration. Heparin therapy alone has not been shown to improve survival [74]. Much attention has been given to replacement of natural anticoagulants such as antithrombin as therapy for purpura fulminans, but randomized trials using antithrombin have shown mostly negative results [75]. Many patients need debridement and amputation; in one review, approximately 66% of patient required amputation [76].

**Drug-Induced Hemolytic-DIC Syndromes**

A severe variant of drug-induced immune complex hemolysis, which may be associated with DIC, has been recognized. The syndrome has occurred in association with the use of advanced-generation cephalosporins (notably cefotetan and ceftriaxone), and it has been reported with carboplatin and oxaliplatin [77]. The clinical syndrome associated with cephalosporin starts 7 to 10 days after receiving the drug and may occur following a single dose given as surgical prophylaxis. The patient develops severe Coombs-positive hemolysis with hypotension and DIC.
The patient may be misdiagnosed as having sepsis and be reexposed to the cephalosporin, resulting in worsening of the clinical picture. The outcome may be fatal because of massive hemolysis and thrombosis.

Quinine is associated with a unique syndrome of drug-induced DIC [78]. Approximately 24 to 96 hours after quinine exposure, the patient becomes acutely ill with nausea and vomiting. The patient then develops a microangiopathic hemolytic anemia, DIC, and renal failure. Some patients, besides having antiplatelet antibodies, also have antibodies that bind to red cells and neutrophils that may lead to the more severe syndrome. Despite therapy, patients will frequently progress to chronic renal failure.

Treatment of the drug-induced hemolytic-DIC syndrome is based on anecdotal reports. Patients have responded to aggressive therapy including plasma exchange, dialysis, and prednisone. Early recognition of the hemolytic anemia (and the suspicion that it is drug-related) is important for early diagnosis so that the culprit drug can be discontinued.

Drug-Induced Thrombocytopenia

Patients with drug-induced thrombocytopenia typically present with very low platelet counts 1 to 3 weeks after starting a new medication [79]. One of the agents most commonly associated with drug-induced thrombocytopenia in the critical care setting is vancomycin. The thrombocytopenia is acute and severe (below $<10 \times 10^9$ per L), is durably refractory to platelet transfusions, and resolves within days of stopping the drug [80]. In patients with a possible drug-induced thrombocytopenia, the primary therapy is to stop the suspect drug. Patients with severe thrombocytopenia should receive platelet transfusions because of the risk of fatal bleeding [81]. However, with vancomycin-induced thrombocytopenia, the patient may be refractory to platelet transfusion [80]. If there are multiple risk medications, the best approach is to stop any drug that is strongly associated with thrombocytopenia (Table 91.8). Immune globulin or corticosteroids have been suggested as useful in drug-related thrombocytopenia. As most patients recover when the agent is cleared from the body, this therapy may not be necessary.

**Sepsis**

Thrombocytopenia associated with sepsis syndromes classically has been attributed to DIC or destruction by autoimmune mechanisms. Increasing evidence points to cytokine-driven hemophagocytosis of platelets [82]. Patients with hemophagocytosis appear to have higher rates of multiple
organ system failure and higher mortality rates. Inflammatory cytokines, especially monocyte-colony stimulating factor, are thought responsible for inducing the hemophagocytosis. Some patients, because of infection, tumors, or autoimmune disease, may develop an overwhelming hemophagocytic syndrome (HPS) [83]. The patient will have pancytopenia, fevers, high ferritins and triglycerides, and low fibrinogens. Mortality is high with HPS, unless there is aggressive treatment.

Thrombocytopenia may be a diagnostic clue to infection with unusual organisms [84]. Three members of the Ehrlichia/anaplasma family have been reported to cause infections in humans [85]. They are transmitted by ticks, and the diseases that they produce are similar. Most patients have a febrile illness with high fevers, headaches, and myalgias [86]. Patients may have central nervous system signs and marked elevation of the serum levels of liver enzymes. Rarely, patients may present with a toxic shock-like syndrome [87]. Although many cases are mild, severe disease is common in immunosuppressed patients. The case fatality rate is 2% to 5% [88]. The typical hematologic picture is leukopenia (1.3 to 4 × 10⁹ per L) and mild thrombocytopenia (30 to 60 × 10⁹ per L). In many patients, the buffy coat reveals the organisms bundled in a 2 to 5 µm morula in the cytoplasm of the granulocytes or monocytes. Consideration of ehrlichiosis is important because highly specific therapy is doxycycline, which is a drug not routinely used for therapy of sepsis syndrome.

The classical hematologic presentation of Hantavirus pulmonary syndrome (HPS) can be helpful in the diagnosis of this severe illness (see Chapter 83). Patients suffer a flu-like prodrome and then rapidly develop a noncardiac pulmonary edema resulting in profound respiratory failure [89]. Ventilatory support is required in 75% of cases and the mortality is approximately 50%. A powerful indicator of the presence of Hantavirus is found on the peripheral smear. The triad of thrombocytopenia, increased and left-shifted white cell count, and more than 10% circulating immunoblasts can identify all cases of HPS and was seen in only 2.6% non-HPS controls. Marked hemoconcentration is also present because of capillary leak syndrome with the hematocrit reaching in some patients as high as 68%.

**Viral Hemorrhagic Fevers**

Viral hemorrhagic fevers (VHF) are a diverse group of viral infections that can result in massive bleeding [90–92]. VHF are an important problem in certain parts of the world, but travelers may carry the disease anywhere. In the southern United States, dengue is becoming an increasing problem, and fatal cases of arenavirus have been reported in California [93]. As described in Table 91.9, there are four groups of viruses which can lead to VHF [94]. The typical pattern is a febrile illness
that proceeds over a few days to shock and diffuse bleeding with the patient developing signs of thrombocytopenia and in some cases DIC. Patients at first presentation often have pharyngitis, conjunctivitis, and a skin rash. A key sign is that patients will experience profuse bleeding from the gastrointestinal tract and mucosal bleeding often out of proportion to the observed coagulation defects. This finding should serve as a diagnostic clue. Most VHF are also associated with leukopenia and hemoconcentration. Therapy is aggressive supportive care of the patients and replacement of coagulation factors. As noted in Table 91.9, ribavirin can treat certain VHF. Given the propensity of many of these infections to spread to health care workers, precautions should be taken to prevent nosocomial spread [95].

Bleeding in the Platelet-Refractory Patient

Bleeding in patients who are refractory to platelet transfusion presents a difficult clinical problem (Table 91.10) [96]. If patients are demonstrated to have human leukocyte antigen antibodies, one can transfuse HLA-matched platelets. Although matched platelet transfusions do not work in 20% to 70% of these patients. Some loci are difficult to match, so effective products may not be available. As many as 25% of patients have antiplatelet antibodies in which HLA-matched products will be ineffective. Platelet cross-matching to find compatible units may not always be successful. In the patient who is totally refractory to platelet transfusion, it is important to consider whether a drug has resulted in antiplatelet antibodies (especially vancomycin) [97]. Use of antifibrinolytic agents such as epsilon aminocaproic acid or tranexamic acid may decrease the incidence of minor bleeding but are ineffective for major bleeding [98]. “Platelet drips” consisting of infusing either a platelet concentrate per hour or one platelethpheresis unit every 6 hours may be given as a continuous infusion [99].
1. Check platelet count 15 min after platelet transfusion.
2. If rise in platelet count is less than $5 \times 10^9$/L, check for HLA antibodies.
3. Administer HLA-matched platelets and evaluate for response.
4. If three sequential HLA-matched platelet transfusions are ineffective, discontinue HLA-matched platelets.
5. In completely refractory patients:
   A. Evaluate for other causes of thrombocytopenia (HIT, drugs).
   B. Consider institution of antifibrinolytic therapy
      1. Epsilon aminocaproic acid 1 gm/h IV, or
      2. Tranexamic acid 10 mg/kg IV every 8 h.
   C. Platelet “drip”—continuous infusion of platelets at the rate 1 unit over 6 h
   D. Recombinant activated VII for life-threatening bleeding

HLA, human leukocyte antigen; HIT, heparin-induced thrombocytopenia; IV, intravenous.

Thrombotic microangiopathies
Catastrophic Antiphospholipid Antibody Syndrome

The patient with catastrophic antiphospholipid antibody syndrome (CAPS) can present with fulminant multiorgan system failure [100]. CAPS is caused by widespread microthrombi in multiple vascular fields. These patients develop renal failure, encephalopathy, adult respiratory distress syndrome (often with pulmonary hemorrhage), cardiac failure, dramatic livedo reticularis, and worsening thrombocytopenia. Many of these patients have preexisting autoimmune disorders and high titer anticardiolipin antibodies. Therapy for these patients includes aggressive immunosuppression, plasmapheresis, and anticoagulation, with consideration of monthly IV cyclophosphamide [100]. Early recognition of this syndrome can lead to quick therapy and resolution of the multiorgan system failure.

Posttransfusion Purpura

Patients with this rare disorder develop severe thrombocytopenia (<10 × 10^9 per L), and often severe bleeding, 1 to 2 weeks after receiving blood products [101]. Affected patients usually lack the platelet antigen PLA1. For unknown reasons, exposure to the antigens from the transfusion leads to rapid destruction of the patient’s own platelets. The diagnostic clue is thrombocytopenia in a patient, typically female, who has received a red cell or platelet blood product in the past 7 to 10 days. Treatment consists of intravenous immunoglobulin [102] and plasmapheresis to remove the offending antibody (see Chapter 96). If patients with a history of posttransfusion purpura require further transfusions, only PLA1-negative platelets should be given.

Venous Thromboembolism and Associated Prothrombotic Disorders in the Intensive Care Unit
ERIC S. CHRISTENSON • SHEETAL KARNE • ASHKAN EMADI • MICHAEL B. STREIFF

INCIDENCE

Venous thromboembolism (VTE), which includes deep vein thrombosis (DVT) and pulmonary embolism (PE), is a common cause of morbidity and mortality affecting over 600,000 Americans each year and causing up to 50,000 deaths [1]. The risk of VTE is particularly high among critical care patients. In the PROTECT trial, a prospective multicenter study of thromboprophylaxis in the intensive care unit (ICU) patients, 7.7% of patients developed VTE despite thromboprophylaxis [2]. Therefore, knowledge of risk factors, as well as evidence-based approaches to prevention and treatment of VTE, is essential for critical care physicians.
Recognizing the conditions that predispose patients to VTE is essential because more than 60% of PE-related deaths occur in patients who go untreated, because the diagnosis was unsuspected and, therefore, undetected [3]. Virtually, all the identified risk factors for VTE can be classified into one of the three classic components of Virchow triad of stasis, venous injury, and hypercoagulability described nearly 150 years ago (Table 92.1) [4,5]. Inherited or acquired thrombophilia states are present in more than 20% of patients with VTE and occur at higher frequency among patients with idiopathic or recurrent VTE (see Table 92.3) [4–6].

Inherited Hypercoagulable Disorders

Factor V Leiden

Factor V Leiden (FVL) is the most common inherited thrombophilic state affecting 5% of European Americans, 2% of Hispanic Americans, 1% of African Americans and Native Americans, and 0.5% of Asian Americans [7]. FVL refers to a point mutation (G1691A), which results in a single amino acid change (Arg506Gln) at the site in the factor V protein where it is cleaved by activated protein C (PC). The mutation markedly slows the rate of inactivation of factor Va by activated PC, leading to more thrombin generation. FVL heterozygosity is associated with a fivefold increased risk of first-ever VTE, whereas homozygosity imparts 80-fold increased risk. FVL does not increase the risk of arterial thromboembolism [8]. FVL heterozygosity and homozygosity increase the risk of recurrent VTE by 1.6-fold and 2.7-fold, respectively [9]. The
activated PC resistance assay is used to screen for the presence of FVL. Commercially available polymerase chain reaction (PCR)–based assays are used to confirm the diagnosis [10].

**Prothrombin G20210A Mutation**

The prothrombin G20210A mutation (PGM) is present in approximately 1% of non-Hispanic whites and Mexican Americans and in 0.3% of African Americans [11]. It is associated with a 30% increase in prothrombin levels in heterozygotes, resulting in a 2.8-fold increased risk of VTE [12]. Although homozygosity is rare, it is associated with a 70% increase in prothrombin levels and imparts a 3.8-fold increased risk of first-ever VTE among carriers [8]. Similar to FVL, the PGM does not increase the risk of arterial thromboembolism [13]. Diagnosis of both FVL and PGM are diagnosed via PCR-based testing of peripheral blood with excellent analytical validity [10].

**Compound Heterozygotes for the Factor V Leiden and Prothrombin G20210A Mutations**

Given the relatively high frequency of the FVL mutation and PGM in the population, compound heterozygosity occasionally is identified. In a systematic review, Segal et al. estimated that the pooled odds ratio (OR) for recurrent VTE in compound heterozygotes was 4.8% [9].

**Protein C Deficiency**

PC is an important endogenous anticoagulant protein that inactivates activated factors V and VIII. Heterozygous PC deficiency affects 0.2% of the general population and 3.2% of unselected patients with their first episode of VTE [14]. It is associated with a sevenfold increased risk of VTE [15]. Homozygous PC deficiency is a rare serious thrombophilic syndrome that causes life-threatening thrombotic complications shortly after birth, a condition called *neonatal purpura fulminans*. Deficiency of PC may be quantitative (type I deficiency) or qualitative (type II). Therefore, accurate diagnostic testing should include both PC activity and antigen levels. Acquired causes of PC deficiency include disseminated intravascular coagulation (DIC), acute thrombosis, vitamin K deficiency, vitamin K antagonist (VKA) therapy (e.g., warfarin), and liver disease. Therefore, diagnostic testing should be performed in the absence of these
conditions to ensure accurate interpretation [16].

**Protein S Deficiency**

Protein S (PS) is the nonenzymatic cofactor for activated PC. PS circulates in two forms: approximately 60% is bound to C4b protein whereas the remaining 40% is free. Only free PS has cofactor activity. The incidence of PS deficiency in the general population has been estimated to be 0.03% to 0.13%. PS deficiency affects 7.3% of unselected patients with venous thrombosis [14]. PS deficiency is associated with an eightfold increased risk of VTE [15], and may be a risk factor for arterial thromboembolism [17,18].

Deficiency of PS may by quantitative (type I deficiency) or qualitative (type II). An additional type of PS deficiency (type III) can be acquired during pregnancy, inflammatory states, and estrogen therapy, which increase C4b protein levels, leading to reduced free PS. Other acquired causes of PS deficiency include vitamin K deficiency, VKA therapy, acute thrombosis, and liver disease. For accurate diagnosis of PS deficiency, tests, including PS activity, total PS antigen, and free PS antigen, should be measured in the absence of conditions associated with acquired PS deficiency [19].

**Antithrombin Deficiency**

Antithrombin (AT) inhibits serine protease coagulation factors by binding to the active site of the target serine protease (e.g., thrombin, activated factors X and IX, etc.) and forming an inactive complex. Heterozygous type I AT deficiency is rare, affecting 1 in 2,000 individuals in the population. It is associated with an 8- to 10-fold increased risk of thrombosis and is present in 1% to 2% of patients with thrombosis [20]. AT deficiency does not increase the risk of arterial thromboembolism [17,18]. Deficiency of AT may be quantitative (type I) or qualitative (type II). Complete AT deficiency is incompatible with life. The diagnosis of AT deficiency is made by measuring AT activity and antigen levels. Acquired AT deficiency may occur in acute thrombosis, DIC, and during heparin therapy. Spurious increases in AT can be seen during therapy with VKA [20].

The use of AT complex (ATC) concentrates as replacement therapy should be limited to conditions with low levels of functional AT and with associated thrombotic imbalance. For example, administration of ATC is recommended for individuals with congenital AT deficiency and for prophylaxis of VTE or treatment of ongoing thrombosis. ATC may also be considered in situations of increased consumption, such as DIC; however, evidence for its use in DIC associated with trauma, burns, or pregnancy,
Dysfibrinogenemia

Dysfibrinogenemia is a rare inherited thrombophilic state caused by mutations in the Aα, Bβ, or γ fibrinogen genes. It affects fewer than 1% of individuals with VTE. Acquired dysfibrinogenemia is associated with chronic liver disease and cirrhosis as well as hepatocellular and renal cell carcinoma. Approximately one-third of cases of dysfibrinogenemia are complicated by thrombosis (venous more commonly than arterial), possibly because of reduced binding to thrombin or inhibition of fibrinolysis. Diagnosis of dysfibrinogenemia is made by measuring fibrinogen function (e.g., Clauss fibrinogen assay) and fibrinogen antigen levels. In dysfibrinogenemia, typically the fibrinogen activity is much lower than the fibrinogen level [22].

Hyperhomocysteinemia

Homocysteine is a thiol-containing amino acid that is converted to methionine by methionine synthase with vitamin B₁₂ and 5-methyltetrahydrofolate as cofactors. Homocysteine is also converted to cysteine by cystathionine β-synthase (CBS) which requires pyridoxine (vitamin B₆) as a cofactor. Congenital causes of hyperhomocysteinemia include homocystinuria (deficiency of CBS) and inheritance of the thermolabile mutation in the methylene tetrahydrofolate reductase (MTHFR) gene [23]. Acquired causes of hyperhomocysteinemia include deficiency of vitamin B₁₂, folate, and pyridoxine, as well as renal insufficiency [24].

Hyperhomocysteinemia has been associated with a 20% increase in cardiovascular disease for each 5 μmol per L increase in fasting homocysteine levels [25]. Homozygosity for the MTHFR mutation is associated with an approximately 1.2-fold increased risk of coronary artery disease [23]. This risk appears to be significantly modified by folate status. Hyperhomocysteinemia is also associated with a twofold to threefold higher risk of initial and recurrent VTE [26,27]. However, randomized studies of vitamin supplementation in patients with venous and arterial thrombotic disease did not demonstrate improved clinical outcomes [28]. The diagnosis of hyperhomocysteinemia is based upon demonstrating elevated levels of homocysteine in a fasting blood sample. Methionine loading prior to sampling can increase the sensitivity of testing.

Elevated Coagulation Factor Levels
Elevated factor VIII (>95 percentile) has been associated with an increased risk of initial and recurrent VTE [29,30]. Elevated factor VIII levels appear to be inherited, but the responsible genetic alterations have yet to be completely characterized. Inflammatory conditions, which are common among patients in the critical care setting, may also transiently raise factor VIII. Elevated factor IX and XI antigen levels have been associated with a 2.5- and 2.2-fold increased risk of initial VTE, respectively [31,32].

**Acquired Hypercoagulable Disorders**

**Surgery**

In the first 6 weeks after an operation, the risk of VTE is 70-fold that of the general population. The risk of VTE gradually declines over time to 20-fold that of the general population in postoperative weeks 7 to 12, 9.4-fold at 4 to 6 months postoperation, and 3.7-fold at 10 to 12 months postoperation. In the Million Women study, hip and knee replacement surgery (7.7 per 1,000 persons-months), cancer surgery (4.4 per 1,000 person-months), hip fracture surgery (3.8 per 1,000 person-months), and vascular surgery (3.1 per 1,000 person-months) were associated with a high risk of VTE [33].

**Ethnicity and Medical Illness**

Ethnicity is an important risk factor for VTE, with Caucasians and African Americans having a higher incidence of VTE than Hispanics and Asians [34]. Immobility is associated with a 9-fold increased risk of VTE [4]. Increased risk is also associated with infectious illnesses such as HIV and autoimmune disorders such as inflammatory bowel disease and systemic lupus erythematosus (SLE) [5]. Chronic hemolytic anemia such as sickle cell anemia and paroxysmal nocturnal hemoglobinuria (PNH) are associated with an increased risk of VTE [35,36].

**Central Venous Catheters**

Indwelling central venous catheters (CVCs), particularly common in critically ill patients, increase the propensity for venous thrombosis through a variety of mechanisms, including endothelial damage, blood flow impedance, and serving as a nidus for clot formation. Symptomatic
CVC-associated deep venous thrombosis occurs in 2% to 6% of patients [37]. The risk is even higher with peripherally inserted central catheters (PICCs) which are associated with thrombosis in 14% of critical care patients [38]. Risk factors for CVC-associated DVT include femoral and subclavian insertion sites, number of catheter lumens and catheter size, PICC versus other CVC, location of catheter tip, history of previous VTE, and presence of active cancer [37]. Among hospitalized patients, the critically ill are at especially high risk for VTE as a result of severe underlying disease, immobility, and CVCs with the incidence of VTE corresponding to the number of risk factors present.

**Cancer**

Cancer is associated with a fourfold to sevenfold increased risk of VTE that varies with the type and extent of cancer and the use of chemotherapy, radiation therapy and growth factors, such as erythropoietic stimulatory agents. Neoplasms of the pancreas, brain, and stomach place patients at high risk for development of thromboembolism, whereas lung and colon cancers are associated with intermediate risk and breast and prostate cancer are associated with a lower risk. Compared to squamous cell carcinoma, adenocarcinoma is associated with a higher risk of thromboembolism. Metastatic disease is associated with a higher risk of thromboembolism than localized cancer [39–41].

Unlike most of the inherited hypercoagulable conditions, cancer is associated with both arterial thromboembolism and VTE. Thromboembolism can be the first sign of an occult malignancy. Unprovoked thromboembolic events are 4.8-fold more commonly associated with the presence of occult malignancy than provoked episodes of thromboembolism [42]. Although routine imaging to detect occult cancer is not associated with a survival benefit in patients with unprovoked VTE [43], we recommend age-appropriate cancer screening (e.g., colonoscopy). Cancer patients are twofold to threefold more likely to suffer recurrent VTE [44]. Low molecular weight heparin (LMWH) has been shown to reduce the incidence of recurrent VTE by 50% in patients with cancer [45]. Therefore, LMWH rather than oral VKAs is considered the agent of choice for long-term management of VTE in cancer patients.

**Myeloproliferative Neoplasms**

Myeloproliferative neoplasms, in particular polycythemia vera (PV), are associated with an increased risk of arterial thromboembolism and VTE that is mediated, at least in part, by erythrocytosis and the associated increased whole blood viscosity, as well as functional abnormalities in
leukocytes and platelets. Risk factors for thromboembolism include age older than 60 years, a previous history of thromboembolism, poorly controlled erythrocytosis, leukocytosis, thrombocytosis, the presence of additional thrombophilic conditions, the JAK2-V617F mutation, and the presence of cardiovascular risk factors, including diabetes, hypertension, hyperlipidemia, and smoking. It is essential to control erythrocytosis in patients with PV, particularly if they are scheduled for surgery. In patients with PV and essential thrombocythemia, aspirin decreases the probability of arterial thromboembolism. In patients older than 60 years of age or those who have prior thromboembolic events, cytoreductive therapy with hydroxyurea, anagrelide, or α-interferon should be strongly considered. Anticoagulation is appropriate for patients who suffer VTE [46,47].

Paroxysmal Nocturnal Hemoglobinuria

PNH is a rare clonal hematopoietic stem cell disorder associated with decreased expression of complement regulatory proteins (CD55 and CD59) on blood cell membranes. This acquired genetic alteration results in chronic intravascular hemolysis, pancytopenia, and a strong predisposition to venous (more common) and arterial (less common) thromboses [48,49]. Unusual locations for thrombosis (e.g., mesenteric vein thrombosis) are not uncommon in PNH patients. The diagnosis of PNH can be confirmed with flow cytometry to detect the presence/absence of CD55 and CD59 (using antibodies) or glycosylphosphatidlyinositol-anchored proteins on the surface of blood cell membranes. Symptomatic patients with significant hemolysis, fatigue, or end-organ damage or thromboembolism should be treated with eculizumab (monoclonal antibody against complement protein C5a). For patients with thromboembolism, conventional anticoagulation is appropriate although it is not always effective in preventing recurrent events. Eculizumab therapy reduces the risk of recurrent thromboembolism by more than 90% [49].

Pregnancy and Postpartum

VTE is a leading cause of death in pregnant women. The age-adjusted risk of VTE is at least fivefold higher compared with nonpregnant women [50]. Pregnancy is accompanied by hormonal changes that increase the prothrombotic potential of the blood that include increases in factor VIII, fibrinogen, von Willebrand factor, and plasminogen activator inhibitor 1 and decreases in free PS. In addition, decreased mobility, increased venous distensibility, and compression of the inferior vena cava (IVC) and iliac veins by the uterus lead to venous stasis. Left leg DVT is more
common owing to disproportionate compression of the left venous system by the gravid uterus [51,52].

The antepartum risk of VTE is highest in the third trimester. The immediate postpartum period is associated with the highest risk which declines to baseline by 12 weeks postpartum [53,54]. Risk factors for VTE during pregnancy include a previous history of VTE, thrombophilia, surgical delivery, age greater than 35 years, obesity, and comorbid medical illness, such as sickle cell anemia [55].

**Heparin-Induced Thrombocytopenia**

Thrombocytopenia affects approximately 20% of patients in the ICU [56]. Although heparin-induced thrombocytopenia (HIT) is uncommon in the ICU [57], prompt recognition and treatment are essential because of the adverse consequences associated with this condition. Surgical patients (particularly, orthopedic and cardiothoracic) are at high risk for HIT, whereas medical patients are at intermediate risk and obstetric and pediatric patients are at low risk [58]. The pretest probability of HIT can be assessed using the “4T score,” a validated clinical prediction rule (see Chapter 91 for the elements of the 4T score and newer proposed clinical tools) [59]. Without treatment, the mortality of HIT is as high as 20% to 25% with a similar percentage of patients surviving with major complications (e.g., stroke or limb loss). Early diagnosis and treatment has improved mortality and morbidity to 5% to 10% [60]. Additional information regarding the pathophysiology and management of HIT is discussed in Chapter 91, “Thrombocytopenia.”

**Major Trauma**

Major trauma is an important cause of VTE in the ICU. Fifty-eight percent of trauma patients develop venographic VTE in the absence of thromboprophylaxis [61]. Trauma is a potent stimulus for clot formation because it impacts all three elements of Virchow’s triad. Patients are immobilized (stasis) for a prolonged period of time and have extensive vascular and tissue damage (vascular wall injury), leading to tissue factor and collagen exposure resulting in activated coagulation (hypercoagulability) [62]. Thromboprophylaxis with enoxaparin (30 mg subcutaneously twice daily), which appears to be more effective than unfractionated heparin (UFH) (5,000 units twice daily), can reduce the incidence of VTE by 50% in major trauma patients [63]. Mechanical prophylaxis with intermittent pneumatic compression devices are a
useful adjunctive measure, if feasible, based on the patient’s injuries. Given the high incidence of VTE, critical care physicians should maintain a high index of suspicion and confirm any clinical findings indicative of thrombosis with objective radiologic testing. Although some have advocated routine radiologic surveillance and prophylactic vena cava filter placement as strategies to reduce VTE in trauma patients, the value of these strategies remains unproven [64,65]. Acute VTE should be managed by conventional anticoagulation. If contraindications present, an optional vena cava filter can be placed until the patient can tolerate anticoagulation.

**Drug-Induced Hypercoagulable Conditions**

Hormonal therapies, including combined estrogen–progestin oral contraceptives and estrogen replacement therapy, are associated with a threefold to fourfold and twofold increased risk of VTE, respectively [66]. The estrogen vaginal ring and oral, as well as depot medroxyprogesterone, also appear to be associated with increased risk. The low-dose progestin intrauterine device thus far has not been associated with increased risk [67]. Selective estrogen receptor modulators tamoxifen and raloxifene; immunomodulatory imide drugs, including thalidomide, lenalidomide, and pomalidomide; erythropoietic stimulatory agents; and atypical antipsychotics, including clozapine, quetiapine, olanzapine, and risperidone; have been associated with an increased risk of thromboembolism [42,68].

Detection of acute thrombosis in a patient receiving one of these medications typically is a sufficient criterion for discontinuation, and the use of such agents in patients with a prior history of thromboembolism must be considered very carefully, weighing the potential benefit against the potential for recurrent thrombosis. In patients whose condition warrants continued treatment with the medication, concomitant anticoagulation should be considered to prevent recurrent thromboembolism. In the MEGA study, resumption of oral contraceptives was associated with more than a twofold increase in recurrence rates compared with patients who did not resume hormonal therapy after an initial hormone-associated VTE [69].

**Antiphospholipid Antibody Syndrome**

The antiphospholipid antibody syndrome (APS) is an acquired, autoimmune thrombophilic disorder that is associated with an increased risk of venous and/or arterial thromboembolism, recurrent pregnancy losses, thrombocytopenia, renal insufficiency, vasculitis, and cardiac valvular abnormalities. APS may be primary (not as a result of any
immediately apparent underlying autoimmune disorder) or secondary, most commonly in association with rheumatologic diseases such as SLE. The diagnostic criteria for APS require the occurrence of one or more objectively documented episodes of thromboembolism or recurrent pregnancy losses in association with positive laboratory testing for lupus anticoagulants (LA) or immunoglobulin G (IgG)/IgM anticardiolipin antibodies or β-2 glycoprotein I antibody performed on at least two occasions 12 or more weeks apart, and at least 23 weeks after the thrombotic event [70].

The prevalence of elevated anticardiolipin antibodies or LAs in the general population varies from 1% to 5%. Approximately 15% to 30% of patients with SLE have an elevated LA and 20% to 40% have an elevated anticardiolipin antibody. The mean age of onset of APS is 31 years. Onset after age 50 is uncommon [71]. In a mixed population of patients with and without SLE, the incidence of thromboembolism in patients with APS was 2.8% per year [72]. In a cohort of SLE patients, 50% suffered a thromboembolic event over 20 years (2.5% per year) [73]. Patients with a positive LA or β-2 glycoprotein I antibodies appear to be at higher risk for thromboembolism than patients with anticardiolipin antibodies [70]. In addition, IgG β-2 glycoprotein I antibodies appear to confer a greater risk of thrombosis than IgM antibodies [72,74]. Triple-positive patients (i.e., patients positive for LAs, β-2 glycoprotein I antibodies, and anticardiolipin antibodies) appear to be at particularly high risk for thromboembolism with 44% suffering thromboembolism over 10 years [75].

The most common manifestation of APS that would bring patients to the ICU is VTE or arterial thromboembolism. A retrospective review of APS patients noted that 59% had VTE, 28% arterial thromboembolism, and 13% both VTE and arterial thromboembolism [76]. In the ICU, the diagnosis of APS is made by objectively confirming clinical manifestations (thromboembolism and pregnancy morbidity) and documenting laboratory evidence of antiphospholipid antibodies.

Treatment of VTE in patients with APS is similar to that for patients with other thrombophilic disorders with several important caveats. APS patients who have an abnormal LA often have baseline prolongation of their activated thromboplastin time (aPTT). If the standard therapeutic range is used in these patients’, UFH may be underdosed. Therefore, patients with a prolonged aPTT at baseline should be treated with an LMWH or have their UFH therapy monitored with an anti-Xa heparin activity assay.

Similar precautions should be taken when considering chronic anticoagulation with a VKA in an LA-positive APS patient. These patients’ LA can prolong the PT/international normalized ratio (INR), giving health care providers the false impression of therapeutic anticoagulation.
Therefore, LA-positive patients starting VKA therapy should have their INR correlated with a chromogenic factor X activity assay (therapeutic range, 20% to 40%) [71,77,78]. This test may also be useful if an APS patient experiences a recurrent thromboembolic event despite conventional intensity anticoagulation. A higher INR target range or alternative anticoagulants (e.g., LMWH, fondaparinux) may be necessary [71,79].

For patients with APS and arterial thromboembolism, we also prefer therapeutic anticoagulation rather than antiplatelet agents. Although one study suggested that aspirin and warfarin were equally effective for arterial thromboembolism, participants did not fulfill criteria for APS [80].

Catastrophic Antiphospholipid Syndrome

Catastrophic antiphospholipid syndrome (CAPS) is a rare (<1% of APS patients) and potentially life-threatening manifestation of APS characterized by multiorgan (kidneys, brain, skin, liver, etc.) dysfunction as a result of diffuse microvascular thrombosis. CAPS is often triggered by infections, major surgery, or discontinuation of immunosuppression or anticoagulation. Almost all patients with CAPS require an ICU level of care. Common manifestations of CAPS-associated organ involvement are displayed in Table 92.2 [81].

<p>| TABLE 92.2 Clinical Manifestations of Catastrophic Antiphospholipid Syndrome |
|-------------------------------|-------------------------------|
| <strong>Organ system</strong> | <strong>Manifestations</strong> |

| Skin      | Livedo reticularis, skin ulcers, digital ischemia, purpura, skin necrosis                                                                    |
| Vasculature | Venous and/or arterial thromboembolism, including deep venous thrombosis, pulmonary embolism, extremity artery thromboembolism, portal vein and inferior vena cava thrombosis, retinal artery and vein thrombosis |

DIC, disseminated intravascular coagulation.

CAPS is thought to be the result of widespread activation of the
endothelium, monocytes, and platelets with tissue factor expression and diffuse activation of the coagulation cascade, resulting in widespread microvascular thrombosis and tissue infarction. The differential diagnosis in patients suspected to have CAPS usually includes severe sepsis, thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, DIC, infectious purpura fulminans, and HIT.

Multimodality therapy is necessary for effective treatment of CAPS. The mainstay of therapy includes anticoagulation (e.g., weight-based UFH titrated to a therapeutic aPTT or anti-Xa heparin level) and immunosuppression with corticosteroids (e.g., intravenous [IV] pulse methylprednisolone 1,000 mg per day for 3 to 5 days followed 1 to 2 mg/kg/d for 2 to 3 weeks). Second-line therapies that are frequently employed in addition to anticoagulation and corticosteroids include IV immunoglobulins (total dose 2,000 mg per kg [400 mg/kg/d for 5 days or 1,000 mg/kg/d for 2 days]), plasmapheresis, and rituximab (375 mg per m² weekly for 4 weeks). Fibrinolytic agents are often used to treat life- or limb-threatening venous or arterial thrombosis. Third-line therapies include cyclophosphamide, prostacyclin (5 ng/kg/min for 7 days [per case reports]), and defibrotide (100 to 275 mg/kg/d for a minimum of 3 weeks). Emerging data suggest that eculizumab may be an effective treatment for CAPS [82].

Treatment of potential precipitating factors of CAPS is also extremely important. Such measures include broad-spectrum antibiotics for infections, aggressive hemodynamic resuscitation in case of shock, debridement or amputation for necrotic tissues, mechanical ventilation, renal replacement therapy, tight glycemic control, stomach acid suppression, and control of malignant hypertension in case of renal artery/vein thromboses. Intravascular instrumentation, especially arterial, should be minimized because of the potential for new clot formation [83].

CAPS mortality rate remains as high as 48% despite all therapies. The clinical manifestations related to poor prognosis and mortality include involvement of the kidney, spleen, lung, and adrenal, as well as history of SLE. Approximately 25% of the survivors will develop further APS-related events, but it is rare to develop recurrent CAPS [83].

Diagnostic Approach to Hypercoagulable Conditions

Because testing for inherited hypercoagulable conditions is expensive and has yet to be demonstrated to significantly influence patient outcomes, there should be a strong clinical rationale for considering thrombophilia testing focusing on individuals likely to benefit from the results. Testing in the setting of an acute thrombosis (including in the critical care setting) is rarely appropriate, with the exception of HIT and APS in
patients with suspected CAPS, because acute thrombosis and its
treatment can influence test results. The summary of appropriate
laboratory tests for hypercoagulable conditions is demonstrated in **Table
92.3**.

ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction.
The precise sequence of events that leads to venous thrombosis is not fully understood and likely varies based on dynamic interactions between genetic and acquired risk factors. In one proposed scheme, blood stasis–induced hypoxia or direct vein wall injury results in endothelial disruption or activation with the exposure of tissue factor on the luminal surface of the vessel triggering initiation of the coagulation cascade, leading to thrombin generation and fibrin deposition \[\text{84,85}\]. Therefore, it is not surprising that many venous thrombi arise in valve pockets where blood flow tends to stagnate, or at a specific area of vascular disruption such as at a CVC insertion site.

Proximal lower extremity DVT is the most frequent source of PE. In untreated patients with proximal DVT, approximately half will go on to develop PE. Other sources of PE include pelvic, renal, or upper extremity veins, as well as the right heart. Embolism to the lungs typically occurs 3 to 7 days after the development of a DVT. After traveling to the lungs, a large thrombus may occlude a major pulmonary artery and cause significant cardiovascular symptoms, or it may break up into smaller clots traveling distally, where it is more likely to produce pleuritic chest pain. Thrombi are most frequently carried to the lower lobes because of preferential blood flow to this location \[\text{86}\].

Hypoxemia results from occlusion of pulmonary vessels and intrapulmonary shunting of blood which leads to an increase in ventilation/perfusion \(\text{V} . / \text{Q} .\) mismatch frequently producing an elevated alveolar-to-arteriolar oxygen gradient. For patients with a patent foramen ovale, progressive pulmonary hypertension may lead to a right-to-left intra-atrial shunt precipitating worsening hypoxemia and, rarely, paradoxic embolization \[\text{87,88}\]. The hemodynamic response to PE varies, depending on the degree of vascular occlusion and the presence of underlying cardiopulmonary disease. The decrease in the cross-sectional area of the pulmonary arterial bed that results from PE leads to increased pulmonary vascular resistance. Pulmonary hypertension suppresses right ventricular (RV) outflow precipitating a reduction in left ventricular (LV) preload and, ultimately, diminished cardiac output and systemic hypotension. Progressive vascular obstruction and hypoxemia promote a vicious cycle of increasing vasoconstriction and further rises in pulmonary artery pressure. The normal right ventricle fails acutely when it cannot generate sufficient systolic pressure to maintain pulmonary perfusion. RV failure typically occurs when mean pulmonary artery pressures rise to greater than 40 mm Hg. Because the pulmonary circulation has a large reserve capacity, more than 50% obstruction is
generally required to precipitate a significant increase in the mean pulmonary artery pressure. Patients with preexisting cardiopulmonary disease have less physiologic reserve than healthy individuals, so they may develop right heart failure with a less significant degrees of pulmonary vascular occlusion [89,90].
PREVENTION

Meta-analyses have demonstrated that pharmacologic VTE prophylaxis reduces the risk of symptomatic DVT, PE, and fatal PE by approximately 50% at the expense of a modest increase in major bleeding [91]. UFH, LMWH, and fondaparinux have all been demonstrated to be effective in medically ill patients [92–95]. Three times-daily UFH may be associated with a greater risk of bleeding than twice-daily UFH [96]. In critically ill patients, dalteparin was associated with a lower risk of DVT than twice-daily UFH [97].

Large prospective multicenter surveys have demonstrated that VTE prophylaxis is underprescribed [98]. Strategies that have been demonstrated to improve prescription of VTE prophylaxis and reduce VTE include computer alerts and mandatory clinical decision support smart order sets [99–101]. Prescription of VTE prophylaxis does not ensure its administration. Retrospective studies have demonstrated that 12% of prescribed doses of VTE prophylaxis are not administered primarily owing to refusal. In 5% of patients, 75% or more of prescribed doses of VTE prophylaxis are not administered [102]. A retrospective study of general surgery and trauma patients found that omission of two or more doses of prophylaxis was associated with a significantly increased risk of VTE [103]. Therefore, identification of strategies to increase VTE prophylaxis administration is an important patient safety priority.

It is important to note that VTE prophylaxis may not have a favorable risk to benefit ratio for all hospitalized patients. Several risk assessment tools have been developed for hospitalized medical (Padua score—expert opinion based and Improve score—evidence based) and surgical patients (Caprini model and Rogers score) [104–107]. The Padua, Improve, and Caprini models have been validated in independent patient populations [108–110]. Given their severity of illness, all ICU patients are likely to benefit from VTE prophylaxis. However, implementation of a VTE prophylaxis order sets that include one of these risk stratification models is likely to improve the risk–benefit balance of VTE prophylaxis and should be considered at all health care facilities (Tables 92.4 to 92.6). Table 92.7 outlines available pharmacologic VTE prophylaxis options.

BMI, body mass index; DVT, deep vein thrombosis; HIT, heparin-induced thrombocytopenia PE, pulmonary embolism; VTE, venous thromboembolism.
TABLE 92.7 VTE Prophylaxis Options

Unfractionated heparin: 5,000 units sc q8–12h
7,500 units sc q8 h (obesity dosing BMI ≥40)

Low Molecular Weight Heparin
Dalteparin 5,000 units sc q24h
7,500 units q24h (obesity dosing BMI ≥40)
(limited data)

Enoxaparin 40 mg sc q24h (general medical and surgical prophylaxis)
Enoxaparin 30 mg sc q24h (renal dosing; creatinine clearance 20–30 mL/min)
Enoxaparin 40 mg sc q12h (obesity dosing BMI ≥40)
Enoxaparin 30 mg sc q12h (orthopedic surgery prophylaxis)

Pentasaccharide
Fondaparinux 2.5 mg sc q24h
Renal dosing: avoid in patients with CrCl <30 mL/min; caution in patients with CrCl 30–50 mL/min

Direct Thrombin Inhibitors
Dabigatran (oral direct thrombin inhibitor)
110 mg orally 1–4 h after hip replacement surgery when hemostasis has been secured, then 220 mg orally once daily for 28–35 d (Avoid in patients with CrCl <30 mL/min or epidural/neuraxial analgesia)

Direct Factor Xa Inhibitors
Apixaban (oral direct factor Xa inhibitor)
2.5 mg orally BID ×35 d starting 12–24 h after hip replacement surgery once hemostasis is secured
2.5 mg orally BID ×12 d starting 12–24 h after knee replacement surgery once hemostasis is secured.
Would avoid in patients with CrCl <25
mL/min or in presence of neuraxial analgesia
Rivaroxaban (oral direct factor Xa inhibitor)
10 mg orally once daily ×35 d starting 6–10 h after hip replacement surgery once hemostasis is achieved
10 mg orally once daily ×12 d starting 6–10 h after knee replacement surgery once hemostasis is achieved
Avoid in patients with CrCl <30 mL/min and those with neuraxial analgesia

Pharmacologic VTE prophylaxis is associated with an increased risk of bleeding which may outweigh its benefits in patients at high risk for bleeding. The IMPROVE survey identified a number of variable associated with an increased risk of bleeding associated with anticoagulants [111]. A validation study of the IMPROVE bleeding risk score is underway. For patients at increased risk for bleeding, intermittent pneumatic compression devices have been shown to reduce the risk of DVT [112]. In contrast, graduated compression stockings do not appear to reduce VTE but do increase the risk of skin breakdown complications [113].
DIAGNOSIS

Recognizing the presence of VTE can be challenging because the signs and symptoms are neither sensitive nor specific for the diagnosis. Consequently, the most important step in diagnosis is maintaining adequate clinical suspicion [86,114]. This goal is best achieved by careful attention to each patient’s constellation of risk factors, symptoms, and signs. Although clinical assessment alone is inadequate to confirm the diagnosis of VTE, both clinical gestalt and clinical prediction rules are useful in establishing the pretest probability of disease in outpatients [45–49]. Clinical pretest probability models such as the Wells criteria and pulmonary embolism rule-out criteria (PERC) serve as the foundation for diagnostic algorithms for DVT and PE (Tables 92.8 to 92.10) [115–117].

DVT, deep vein thrombosis; PE, pulmonary embolism.

Diagnosis of VTE in the critically ill patient can be particularly challenging because underlying chronic systemic illnesses, as well as superimposed acute illnesses may mimic or mask the typical signs and symptoms of VTE. In addition, common clinical prediction models for VTE may not be valid in the ICU setting [118]. Furthermore, objective testing for VTE may be precluded by relative contraindications, such as mechanical ventilation, shock, and renal failure.

---

**Symptoms and Signs**

Although most DVT begin in the calf, the presenting symptoms and signs are often not noted until more proximal veins are involved [86]. The initial clinical manifestations of DVT may include warmth, erythema, swelling, and pain or tenderness and may be acute, progressive, or
resolve spontaneously. Cellulitis, trauma, Baker cyst, or musculoskeletal pain can all cause signs and symptoms similar to acute DVT.

Most patients with acute PE present with at least one of the following: dyspnea, pleuritic chest pain, or tachypnea. Other findings may include tachycardia, a loud pulmonic component of the second heart sound, fever, crackles, pleural rub, and/or wheezing. Pleuritic chest pain and hemoptysis occur more commonly with pulmonary infarction as a result of smaller, peripheral emboli. PE must always be considered in cases of unexplained dyspnea, syncope, or sudden hypotension. Symptoms and signs of PE are nonspecific and can be frequently seen in patients with other cardiopulmonary diseases, including pneumonia, chronic obstructive lung disease exacerbation, pneumothorax, myocardial infarction, heart failure, pericarditis, musculoskeletal pain or trauma, pleuritis, malignancy, and, occasionally, intra-abdominal processes such as acute cholecystitis or nephrolithiasis.

Given the potential for rapid clinical decompensation and the significant associated morbidity and mortality, clinicians must maintain a high index of suspicion for PE in the ICU. Subtle signs such as worsening hypoxemia, a reduction in arterial carbon dioxide with spontaneous respirations (especially in a patient with chronic lung disease), increased central venous or pulmonary artery pressure, or unexplained fever should all be considered potential heralds of PE. Even in the presence of alternative diagnoses, evaluation for possible VTE may still be appropriate when suggestive signs, symptoms, and risk factors are present [119,120].

Clinical Prediction Models

Clinical pretest probability models are useful for assessing a patient’s risk for VTE and determining the appropriate course for further evaluation. The most widely studied and validated models are the Wells score and the Geneva Rule (Tables 92.8 to 92.10) [115,116,121]. The major distinction between these two preclinical probability models is that the Geneva Rule consists of completely objective criteria whereas the Wells score incorporates clinical judgment as to whether PE is the most likely etiology of the patient’s symptoms. When these models were compared head-to-head, there were no major differences in diagnostic accuracy or negative predictive value for the exclusion of VTE [122]. All scoring systems performed well in combination with D-dimer measurement to identify a low-risk population that did not require radiologic testing to
exclude VTE [123]. The PERC is a clinical decision support tool developed by Kline and coworkers to identify outpatients presenting with chest pain who are thought to be at low risk for PE in whom further diagnostic testing can be avoided (Table 92.11) [117]. A recent meta-analysis of 12 studies encompassing over 14,000 patients confirmed the accuracy of the PERC [124]. Consequently, the PERC was included in the American College of Physician’s Practice Guideline on the diagnosis of PE [125].

D-Dimer

Quantitative plasma measurements of D-dimer (a fragment of cross-linked fibrin) have been extensively studied in patients with acute DVT and PE. Although multiple inexpensive D-dimer tests are available, rapid quantitative enzyme-linked immunosorbent assays are preferred because of their high sensitivity [126]. In conjunction with pretest probability models, sensitive enzyme-linked immunosorbent assay D-dimer tests
measurements have been demonstrated to safely exclude the presence of DVT and PE in outpatients judged to be at low risk for VTE [115,116,121]. Unfortunately, d-dimer levels are elevated by a large number of clinical conditions (including cancer, inflammation, infection, pregnancy, and recent surgery) which makes the test less useful in unselected and hospitalized patients [127]. For these cases, objective radiologic testing is necessary to confirm/exclude the diagnosis [128]. Because d-dimer levels increase with age, age-specific d-dimer cutoffs have been proposed to increase the utility of d-dimer testing in older adults. This approach has been noted in a meta-analysis by Schouten et al. to lead to increased specificity for individuals older than 50 years of age while maintaining excellent sensitivity [129].

Diagnosis of Acute Deep Venous Thrombosis

Compression venous ultrasonography is the preferred noninvasive test for the diagnosis of symptomatic proximal DVT, where it has a weighted sensitivity and specificity of 95% and 98%, respectively [130]. Although it is generally appropriate to initiate or withhold treatment based on the result of the examination, an exception would be when the result is discordant with the clinical assessment. For instance, a negative compression ultrasound in the context of a high clinical suspicion for DVT would warrant further investigation, such as venography, magnetic resonance imaging (MRI), or computed tomographic venography (CTV). Duplex ultrasonography is also useful for detecting upper extremity DVT. Limitations of venous ultrasonography include insensitivity for asymptomatic DVT and pelvic vein clots, dependence on operator skill, and difficulty distinguishing acute from chronic DVT in symptomatic patients [131].

MRI and CTV are being increasingly employed to diagnose DVT. MRI is highly accurate and has multiple advantages, including excellent resolution of the IVC and pelvic veins, accuracy in diagnosing upper extremity DVT, concurrent thoracic as well as bilateral examination, differentiating acute from chronic disease, and lack of exposure to ionizing radiation [132]. However, MRI is expensive, time-consuming, not portable, and is restricted in patients with metallic devices or claustrophobia. As with MRI, computed tomographic angiography (CTA)/CTV has the advantage of evaluating both PE and DVT in a single study. CTV is accurate in the detection of DVT and may be particularly useful in imaging the pelvis and upper thighs [132]. In the PIOPED II, concurrent leg evaluation with CTV increased the sensitivity of CTA from 83% to 90%, although the small improvement in overall diagnostic yield may not warrant the additional irradiation associated with CTV [133]. Contrast venography is rarely done anymore.
Diagnosis of Acute Pulmonary Embolism

Contrast-enhanced chest CTA is the imaging procedure of choice for PE because it has the capacity to reveal emboli in the main, lobar, segmental, and subsegmental pulmonary arteries, as well as other diseases of the thorax that can mimic PE. In patients with an intermediate or high probability of PE, an abnormal CTA has a positive predictive value of 92% and 96%, respectively. In patients with a low clinical likelihood of PE, normal findings on CTA had a 96% negative predictive value supporting the use of multidetector CTA as stand-alone imaging for suspected PE in the majority of patients. This modality can be used in combination with D-dimer to screen low- to intermediate-risk patients with excellent negative predictive value [134].

Unfortunately, 5% to 8% of CTAs are technically inadequate owing to motion artifact or inappropriate contrast timing [128]. Therefore, in such an instance, PE should not be prematurely dismissed as a diagnostic possibility in the context of a high clinical probability. When compared head-to-head with (V / Q) scanning, CTA was shown to identify more patients with PE although the clinical significance of these additional identified PE has not been elucidated [135]. CTA also has the advantage of rapid performance. The disadvantages of CTA include the risk of adverse reactions to contrast (such as anaphylaxis or nephrotoxicity) and lack of portability. ICU patients frequently have a prohibitive creatinine clearance.

Although chest CTA is a superior imaging test for PE, V / Q. scanning is still utilized in select cases of suspected PE. V / Q. scans are typically interpreted as being normal or low, intermediate, or high probability of PE. A normal scan essentially excludes the diagnosis of PE. In the PIOPED study, when the clinical suspicion of PE was high, PE was present in 96% of patients with high-probability lung scans. However, in patients with a high clinical pretest probability for PE, 66% of patients with intermediate-probability scans and 40% of patients with low-probability scans were subsequently diagnosed with PE by pulmonary angiography [136]. This emphasizes that low- and intermediate-probability V / Q. scans are frequently nondiagnostic when there is a high clinical suspicion for PE. However, in the setting of a low clinical pretest probability for PE, a normal or low-probability V / Q. scan correctly excluded PE in more than 95% of cases. V / Q. scans are typically used for PE imaging in patients with contrast allergies or those at risk for contrast nephrotoxicity and in pregnant patients to reduce radiation exposure [128].

p. 863

p. 864
MRI has excellent sensitivity and specificity and may allow the simultaneous detection of DVT and PE. However, MR angiography and MR venography are technically difficult, leading to inadequate results in 52% of patients in the PIOPED III study [137]. This modality should, therefore, only be considered in centers that routinely perform this study in patients with contraindications to standard testing.

Pulmonary artery angiography is sensitive and specific test for confirming or excluding acute PE and remains the “gold standard” diagnostic technique. In 1,111 cases from the PIOPED study, 3% of studies were nondiagnostic and 1% were incomplete, usually owing to a complication. Although complications are more common in the ICU, angiography is generally deemed quite safe, with major morbidity and mortality rates of 1% and 0.5%, respectively. Serious complications include respiratory failure (0.4%), renal failure (0.3%), and hemorrhage requiring blood transfusion [138]. Pulmonary angiography is generally reserved for patients in whom less invasive testing has been nondiagnostic. To avoid the potential complications associated with angiography, lower extremity duplex ultrasound is often performed in lieu of angiography in the diagnosis of patients with suspected but unconfirmed PE.

An Integrated Approach to Venous Thromboembolism Diagnosis

To minimize patient exposure to ionizing radiation and overall health care costs, an efficient and cost-effective approach to VTE diagnosis integrates pretest probability models such as the Wells criteria and PERC, D-dimer testing, and imaging. In conjunction with D-dimer testing, the Wells criteria have been demonstrated to safely exclude VTE in outpatients with suspected thromboembolism. The PERC facilitate identification of low-risk patients in whom PE can be ruled out without imaging. A schematic depiction of the use of the Wells criteria and the Geneva Score in conjunction with the PERC and D-dimer testing in the diagnosis of DVT and PE is displayed in Figures 92.1 and 92.2.
FIGURE 92.1 Diagnostic algorithm for DVT. DVT, deep vein thrombosis.
Risk Stratification

Risk stratification is essential to selection of the appropriate treatment strategy. PE has traditionally been classified into massive, submassive, and normal risk on the basis of hemodynamic compromise along with the presence/absence of ventricular strain. Massive PE is defined by the presence of hypotension with a systolic blood pressure of 90 mm Hg or less or the need for vasopressors to maintain adequate end-organ perfusion. Massive PE necessitates prompt intervention and constitutes a medical emergency [128].

Submassive PE is characterized by evidence of RV dysfunction as documented by echocardiography, CT scan, elevated right heart pressure on cardiac catheterization, or elevated natriuretic peptide or troponin measurements. These patients are at increased risk for the development of hemodynamic compromise and are often monitored as inpatients initially. Patients without these features are considered normal risk and can be discharged for outpatient management [128].

Several evidence-based risk stratification tools have been developed to identify PE patients at low risk for complications who can be managed as outpatients, including the Pulmonary Embolism Severity Index (PESI) (Table 92.12) and the HESTIA criteria (Table 92.13) [139,140]. Of these, the PESI score and a simplified version, sPESI, have been the most extensively validated. In a multicenter, prospective, open randomized clinical management study, Aujesky et al. found that the PESI score was able to identify low-risk PE patients who did equally well whether managed as inpatients or outpatients [141]. The HESTIA criteria have also been demonstrated to be useful in identifying patients for outpatient management [142].

A total point score for a given patient is obtained by summing the patient’s age in years and the points for each applicable predictor. Points assignments correspond with the following risk classes: Class I (very low risk): ≤65; Class II (low risk): 65–85; Class III (intermediate risk): 86–105; Class IV (high risk): 106–125; Class V (very high risk): >125.

<sup>a</sup> Chronic obstructive pulmonary disease with and without supplemental oxygen administration.

<sup>b</sup> Altered mental status was defined as confusion, disorientation, somnolence, lethargy, stupor, or coma. PESI, Pulmonary Embolism Severity Index.

</table>
Thrombolysis or embolectomy necessary
High risk of bleeding (e.g., GI bleed within 14 d, recent stroke within 4 wk, recent surgery within 2 wk, platelets <75,000/µL, uncontrolled HTN: systolic BP >180 mm Hg, diastolic BP >110 mm Hg)

Supplemental O₂ needed to keep O₂ saturation >90% for >24 h
Pulmonary embolism during anticoagulation treatment
Intravenous pain medication >24 h
Medical or social reason for in-hospital treatment >24 h
Creatinine clearance <30 mL/min
Severe liver impairment
Pregnant
Documented history of HIT

The presence of any criterion precludes outpatient treatment.
BP, blood pressure; ICU, intensive care unit; GI, gastrointestinal; HIT, heparin-induced thrombocytopenia; HR, hazard rate; HTN, hypertension.

Because right ventricular enlargement (RVE) is an important marker of thrombus burden and hemodynamic compromise resulting from PE, imaging studies such as echocardiography and CT have also been used for risk stratification of PE patients. In a retrospective study of 431 patients with PE, RVE on CT was an independent predictor of 30-day mortality (hazard ratio: 5.17; 95% CI 1.63 to 16.35) [143]. A meta-analysis of 10 studies of normotensive PE patients determined that CT RVE was associated with an overall increased risk of death (OR 1.8; 95% CI 1.3 to 2.6), death as a result of PE (OR 7.4; 95% CI 1.4 to 39.5), and PE-related complications (OR 2.4; 95% CI 1.2 to 4.7) [144]. However, CT only demonstrated modest utility in identifying patients at risk for complications and, therefore, should not be used in isolation for determining management.

Echocardiography has also been used to determine RV overload for the purposes of PE prognostication. However, a meta-analysis noted that echocardiography had an unsatisfactory negative likelihood ratio for early
all-cause mortality (0.62; 95% CI 0.41 to 0.92) and PE-related mortality (0.36; 95% CI 0.20 to 0.80). This outcome may reflect the lack of standardized echocardiographic criteria for RV dysfunction and the difficulty in differentiating between acute and chronic RV overload [145]. Therefore, it is currently premature to rely upon echocardiography to identify low-risk patients with PE.

Cardiac biomarkers such as troponin I and T and NT-pro-BNP that are released from myocytes during RV strain have also proven useful for prognostication of PE patients. In a multicenter prospective study, Vuilleumier and colleagues found that an NT-pro-BNP level <300 pg per mL had a negative predictive value of 100% (95% CI 91 to 100) for adverse outcomes from PE at 3 months [146]. In a prospective validation study 7 of 526 normotensive PE patients, Lankeit et al. noted that only 4 of 214 (1.9%) patients with a high sensitive troponin T <14 pg per mL had adverse outcomes at 30 days. When combined with an sPESI score of zero, none of 127 patients with this combination had adverse outcomes [147].

A combination of clinical and laboratory biomarkers may represent the ideal strategy for identification of normotensive patients at low risk for adverse outcomes. Jimenez et al. conducted a multicenter cohort study of normotensive PE patients to identify a multimarker prognostic score for risk stratification. The combination of an sPESI and a brain natriuretic peptide level <100 pg per mL was associated with a negative predictive value of 99% and 100% in the derivation and validation cohorts, respectively [148].

PE patient management should be guided by an assessment of their risk for adverse outcomes (Table 92.14). Normotensive patients in PESI class ≥ II or sPESI ≥1 should undergo additional imaging and laboratory risk assessment and warrant initial inpatient management until the results of these studies are complete. Patients in this group who have no sign of RV dysfunction on echocardiography or abnormal cardiac biomarkers are considered at low intermediate risk for adverse outcomes. This group of patients can be considered for early discharge from the hospital. Patients with abnormal echocardiography or cardiac biomarkers are considered intermediate–low-risk patients and are often managed in the hospital. Patients with abnormal echocardiography and cardiac biomarkers are considered at intermediate high risk of adverse outcomes and are generally managed as inpatients. Intermediate–high-risk PE patients are considered for thrombolytic therapy on a case-by-case basis. PE patients with hypotension are at high risk for adverse outcomes. They
routinely undergo echocardiography and are strongly considered for thrombolytic therapy (Table 92.12) [128].

TREATMENT

Treatment for VTE centers on the use of anticoagulation to prevent clot propagation and promote the body’s natural thrombolytic processes to resorb the clot and allow for vessel recanalization (Table 92.15) Other treatment options include thrombolytic therapy, IVC filter placement, and surgical embolectomy. Each approach has specific indications as well as advantages and disadvantages. Initiation of therapy should usually be delayed for confirmatory testing in most clinical scenarios. Exceptions to this principle includes patients with high clinical pretest probability, moderate pretest probability where the results of diagnostic testing will be delayed for hours, or clinical scenarios where delaying therapy would lead to high likelihood of an adverse outcome [149].

**Anticoagulation**

Anticoagulants do not directly dissolve preexisting clot; instead, they prevent thrombus extension and indirectly decrease clot burden through...
the body’s endogenous fibrinolytic system. Information regarding pharmacokinetics and dosing of traditional anticoagulants such as UFH, the LMWH, fondaparinux, and warfarin can be found in Chapter 93. For critically ill ICU patients, UFH is the parenteral anticoagulant of choice given its short half-life and complete reversibility with protamine. Multiple clinical trials have demonstrated that LMWH is a safe and effective alternative to UFH for the treatment of acute VTE that does not require laboratory monitoring [150]. Similarly, fondaparinux, a synthetic pentasaccharide, is as effective as LMWH and UFH in the initial treatment and prevention of VTE [151]. Although fondaparinux is an attractive agent for outpatient anticoagulation because of its extremely rare association with HIT, it is often an impractical anticoagulant in ICU patients owing to its long half-life, renal elimination, and the absence of an available reversal agent.

Except for those with active cancer, most VTE patients will be transitioned from parenteral therapy to warfarin or a direct oral anticoagulant for short- or long-term treatment. Because warfarin requires at least 5 days to achieve therapeutic anticoagulation, initial coadministration with a rapid-onset parenteral anticoagulant such as UFH or LMWH is necessary when initiating therapy. Failure to employ a parenteral agent during initial warfarin therapy is occasionally complicated by warfarin skin necrosis, a procoagulant state characterized by thrombosis of dermal vessels and skin ulceration with a predilection for adipose-laden areas of the body. Therefore, it is recommended that parenteral anticoagulants continue until an INR of 2 or more has been achieved for at least 24 hours [152,153].

Dabigatran is an oral direct thrombin inhibitor that is the Food and Drug Administration (FDA) approved for treatment of VTE and thromboprophylaxis in nonvalvular atrial fibrillation and orthopedic VTE prophylaxis (see Chapter 93 for information regarding pharmacokinetics and approved dosing). In the RECOVER trials, dabigatran was demonstrated to be as effective and safe as warfarin for prevention of recurrent thromboembolism in patients with acute VTE following at least 5 days of therapy with a parenteral anticoagulant [154,155]. In the past 4 years, three oral direct factor Xa inhibitors have been approved by the FDA for treatment of VTE, apixaban, edoxaban, and rivaroxaban (see Chapter 93). In the AMPLIFY study, apixaban was as effective as LMWH/warfarin for the first 6 months of therapy of acute VTE [156]. In the AMPLIFY-EXT study, Agnelli and colleagues demonstrated that apixaban 2.5 mg twice daily was superior to placebo in
prevention of recurrent VTE and associated with a similar risk of clinically relevant nonmajor bleeding for long-term therapy (>6 months) of VTE [157]. In the EINSTEIN studies, rivaroxaban was demonstrated to be as effective as LMWH/VKA in the treatment of initial and long-term therapy of VTE [158,159]. Edoxaban is an oral factor Xa inhibitor that was compared with warfarin for treatment of VTE in the HOKUSAI study. Similar to dabigatran, edoxaban was preceded by a 5- to 10-day course of parenteral therapy [160]. Therefore, initial parenteral therapy should be employed for at least 5 days when using edoxaban or dabigatran for treatment of VTE.

Although each of the direct oral anticoagulants have been demonstrated to be as safe and effective as conventional anticoagulation for treatment of VTE, the long half-lives of these medications, their dependence on renal and/or hepatic function for clearance, and the absence of readily available laboratory tests for monitoring and a reversal agent for bleeding complications makes them less attractive agents for critically ill patients.

Thrombolytic Therapy

In patients with PE, systemic thrombolytic therapy is reserved for patients with massive PE characterized by the presence of hypotension (systolic blood pressure <90 mm Hg) and hypoxemia (room air O₂ saturation <90%) in whom mortality rates can be as high as 58% [161]. Thrombolytic therapy is not generally used in patients with submassive PE. In two randomized controlled trials in patients with submassive PE, thrombolytic therapy prevented clinical deterioration but was not associated with a mortality benefit and increased bleeding complications so it should be reserved for patients with massive PE [162,163]. The standard thrombolytic regimen for PE is alteplase 100 mg over 2 hours with 10 mg administered as a bolus at the initiation of therapy. (Table 92.14) Lower dose alteplase regimens should be considered for older patients (age >65 years) who are at higher risk for bleeding complications [128]. The decision for thrombolysis should be made on a case-by-case basis. Even in the setting of a relative contraindication, thrombolytic therapy may be reasonable when a patient is extremely unstable from life-threatening PE.

Catheter-directed thrombolysis (CDT) using the EKOS ultrasound catheter may be a useful option for patients with massive or submassive PE deemed at high risk for bleeding who are also at high risk for clinical deterioration as a result of their PE. The EKOS catheter uses ultrasound to disrupt the structure of the thrombus while spraying the thrombolytic agent locally into the substance of the clot via side holes in the catheter. Preliminary studies of the “EKOS” catheter indicate that it may accelerate
clot resolution with a low risk of major bleeding [164,165]. Further investigation of the EKOS catheter is warranted to confirm its impact on clinical outcomes.

In an arrest or a periarrest situation, the use of thrombolytics is often considered in an attempt to improve hemodynamics and reverse/prevent hemodynamic collapse. There is some evidence for improved outcomes with this approach in patients with a confirmed or strongly suspected PE [128,166]. However, empiric use in a trial evaluating administration in undifferentiated out-of-hospital arrests showed no significant improvement in mortality [167].

Each of the FDA–approved thrombolytic agents is administered at a fixed dose, making measurements of coagulation unnecessary during infusion (Table 92.16). Tissue-type plasminogen activator (2-hour infusion) is most commonly used. Shorter regimens and even bolus dosing may be favored in cases of unstable patients with massive PE. Following infusion of thrombolytics, the aPTT should be measured and repeated at 4-hour intervals until the aPTT is less than twice the upper limit of normal, after which continuous IV UFH should be administered without a loading bolus dose.

a Limited availability.

Thrombolytic therapy is contraindicated in patients at high risk for bleeding (Table 92.17). Intracranial hemorrhage is the most devastating (and often fatal) complication of thrombolytic therapy and occurs in 1% to 3% of patients [161,168,169]. Invasive procedures should be minimized around the time of therapy to decrease the risk of bleeding.

| IV, intravenous; PE, pulmonary embolism; tPA, tissue plasminogen activator. |
In patients with deep venous thrombosis, CDT is generally reserved for patients with massive or limb-threatening iliofemoral deep venous thrombosis. In the CAVENT study, an open randomized controlled trial of CDT versus conventional anticoagulation in iliofemoral DVT, CDT was associated with more rapid resolution of thrombus burden and a reduced incidence of post-thrombotic syndrome [170]. In patients with May–Thurner syndrome (iliac vein compression syndrome), CDT in conjunction with angioplasty and venous stenting has been advocated as the preferred approach to therapy although supportive data are limited to retrospective case series [171]. Randomized studies should be performed before this is considered standard therapy. The benefits of CDT include more rapid and complete reduction of thrombus burden and associated clinical symptoms, as well as the potential to reduce venous valvular
damage and the incidence of post-thrombotic syndrome. The primary risk associated with thrombolytic therapy is an increase in bleeding complications. The ongoing ATTRACT trial should help to answer some of the outstanding questions surrounding thrombolytic therapy for DVT [172]. Until these data are available, CDT should be reserved for patients with extensive proximal clots with low bleeding risk.

**Inferior Vena Cava Interruption**

IVC filters are metallic wire devices often constructed of flexible nonferromagnetic alloys that designed to catch large clots that could cause life-threatening pulmonary emboli. Although originally designed for permanent placement, most current IVC filters are designed to be retrieved. Because permanent and retrievable filters appear to have similar efficacy and safety and most patients have transient contraindications to anticoagulation, it is preferable to use retrievable filters that afford the option of later retrieval [173].

The only widely accepted indication for IVC filter placement is a contraindication to anticoagulation in a patient with acute (within 1 month) proximal deep venous thrombosis with or without PE. Because the risk of recurrent VTE is substantially lower in patients with less acute DVT (10% during months 2 to 3), the use of IVC filters in this patient population is likely to be associated with less attractive risk to benefit balance particularly if the contraindication to anticoagulation is temporary. It remains unclear if IVC filters are beneficial in patients with isolated PE without evidence of proximal DVT or IVC thrombosis [173].

Although the data are not conclusive, several studies suggest that the Trapease (permanent filter) and Optease (retrievable filter) are associated with a greater risk for filter-related IVC thrombosis perhaps owing to its opposing dual cone filter design [174]. Therefore, we would suggest that health care providers avoid use of these filters. If a retrievable filter is placed, it is incumbent upon the responsible physicians to ensure that the filter is removed as soon as it is no longer needed because many filters are left in place unnecessarily. It is particularly important to retrieve filters with a short retrieval window such as the Optease filter (within 3 weeks).

IVC filters are likely to reduce the incidence of PE in patients who cannot be anticoagulated [175]. In patients who can be treated with anticoagulation, filters do not reduce the incidence of PE or improve mortality [176]. They are associated with a 1.5-fold increased risk of deep venous thrombosis and a cumulative incidence of IVC thrombosis of 14% at 8 years of follow-up [177]. Anticoagulation likely reduces the risk of deep venous thrombosis associated with IVC filters, therefore anticoagulation should be considered in appropriate candidates. There is
limited literature on the risks and benefits of SVC filters. Because the PE is less common in patients with upper extremity thrombosis, the use of filters in this position is discouraged [173].

**Pulmonary Embolectomy**

Given its high morbidity and mortality, surgical embolectomy has traditionally been a treatment of last resort, often reserved for patients with documented central PE and refractory cardiogenic shock despite maximal therapy. Contemporary studies show improved outcomes with in-hospital mortality as low as 5% to 6% and suggest that emergency surgical pulmonary embolectomy may be feasible in carefully selected patients and with an experienced surgical team [178]. Catheter-directed embolectomy and/or the localized administration of thromblytics is an emerging treatment modality shown to improve hemodynamics by reducing the burden of central pulmonary artery thromboembolism. Ultrasound has been used as an adjunct to this approach with the idea of destabilizing the clot and increasing the efficacy of thrombolytic therapy [164,165,179].

**Adjunctive Care for Massive Pulmonary Embolism**

The mere suspicion of massive PE warrants immediate supportive therapy. A cautious fluid challenge of IV saline may augment preload and improve impaired RV function. Dopamine and norepinephrine are favored if hypotension remains, and combination therapy with dobutamine may boost RV output, although it may exacerbate hypotension. Additionally, clinicians must be cautious that augmenting cardiac output above physiologic levels may exacerbate (V : Q) mismatch by shunting blood from areas with partially obstructed vessels. Supplemental oxygen and mechanical ventilation may be instituted as needed to support respiratory failure. Inhaled nitric oxide may improve the hemodynamic status of patients while avoiding the potentially deleterious effects of IV agents on systemic blood pressure [128]. Thrombolytic therapy or pulmonary embolectomy should be considered followed by anticoagulation as previously described.
Central Venous Catheter–Associated Thrombosis

Symptomatic catheter-related thrombosis are felt to occur in up to 6% of adults with conventional CVC and 14% with PICC [37,38], and upper extremity thrombosis is common complication in critically ill patients primarily because of the wide spread use of CVCs. CVC-associated DVT is generally treated with anticoagulation for at least 3 months or until the CVC is removed whichever is longer. If the CVC is still needed for patient care, there is no need to remove the catheter unless symptoms fail to improve with anticoagulation. Thrombolytic therapy is reserved for limb-threatening or extremely symptomatic CVC-associated DVT that has not responded to standard therapy in candidates without contraindications. CVC removal is consider as primary therapy for patients who are not candidates for anticoagulation although it should be noted that this approach is probably associated with a higher risk of embolization in the absence of at least a week of anticoagulation. Complications of CVC-associated thrombosis include catheter infections, PE, post-thrombotic syndrome, catheter dysfunction, and persistent vascular compromise [180]. Symptomatic PE occurs in 3% to 12% of adult patients with an upper extremity DVT. The risk of clot embolization that accompanies CVC extraction is outweighed by the risk for chronic thrombotic complications and potential infection. Upper extremity DVTs have a substantially lower rate of recurrence than those in the lower extremities [37].

Pregnancy-Associated VTE

The diagnosis of VTE during pregnancy is complicated by physiologic changes in the mother and the presence of the fetus which limit the use of radiographic imaging. d-Dimer levels tend to be elevated during pregnancy which limits the diagnostic utility of the test. Chan and colleagues developed a pretest probability score for DVT diagnosis called the LEFT model [181] that may reduce the need for diagnostic testing; if testing is required, however, noninvasive methods such as lower extremity duplex ultrasonography should be used initially. If the duplex ultrasound is nondiagnostic, to assess for PE, a chest radiograph should be ordered to look for active pulmonary disease. In the setting of a
normal chest X-ray, a (V/Q) scan may be performed. Conversely, a CTA with abdominal shielding should be ordered if the chest radiograph is abnormal [182]. Interestingly, data suggest that a chest CT may deliver less radiation to a fetus than a (V/Q) scan when performed during the first or second trimester [128].

Weight-adjusted LMWH is the principal therapy for VTE during pregnancy because warfarin and direct oral anticoagulants are contraindicated. UFH is preferred by some health care providers after 36 weeks of gestation because of its complete reversibility with protamine. Warfarin can be used in the postpartum period because it does not appear to be secreted in clinically relevant concentrations in breast milk. Thrombolytic therapy is relatively contraindicated because of the potential risk of maternal hemorrhage and fetal demise. However, thrombolytic therapy should not be withheld in cases of massive PE when its use may be lifesaving. IVC filters are limited to pregnant patients with acute proximal DVT and contraindications to anticoagulation. Prophylactic anticoagulation is used in patients who are at high risk for recurrent VTE during pregnancy, such as those on anticoagulation prior to pregnancy, patients with a history of estrogen- or pregnancy-associated VTE, and patients with high-risk thrombophilia [183].
SEQUELAE OF VENOUS THROMBOEMBOLISM

VTE is associated with several sequelae, including nonfatal recurrent VTE, post-thrombotic syndrome, chronic thromboembolic pulmonary hypertension, and fatal PE. Death occurs in approximately 6% of DVT cases and 12% of PE cases within 1 month of diagnosis [184]. In the ICOPER study, the all-cause 3-month mortality rate was 17.4% [161]. In the PIOPED study, all-cause mortality at 3 months was 15%, but only 10% of deaths during the first year of follow-up were attributable to PE [185]. The risk of death is as high as 58% in patients with massive PE [161]. During the initial 3 months of therapeutic anticoagulation, 4% of patients with proximal DVT will suffer a recurrent episode of VTE, and about 1 in 250 will develop fatal PE [186]. In addition, about 3% to 4% of PE patients will develop chronic thromboembolic pulmonary hypertension. Chronic thromboembolic pulmonary hypertension (CTEPH) is increased in patients with larger perfusion defects, younger patients, and patients with recurrent PE. In patients with suspected CTEPH or at high risk for CTEPH should undergo echocardiography and (V. / Q. ) scanning. Right heart catheterization is recommended for accurate determination of pulmonary artery pressures. CTEPH can be managed medically with vasodilators such as IV epoprostenol and oral bosentan and sildenafil. For patients with severe pulmonary hypertension not responsive to medical therapy, pulmonary thromboendarterectomy is recommended. The University of California at San Diego has the world’s largest experience with this surgery and has published very good outcomes with this procedure [187].

Duration of Anticoagulation

Although decision-making regarding the appropriate duration of therapy for VTE is not often an immediate concern for critical care physicians, an understanding of the current treatment approach can be valuable when caring for critically ill patients who suffer complications of anticoagulant therapy. Currently, the duration of therapy for VTE is largely dictated by the clinical circumstances of the thrombotic event. Unprovoked VTE is associated with a high risk of recurrence (~7% per year) after completion of a standard course of anticoagulation, whereas VTE associated with a major surgical procedure are associated with a low risk of recurrence (0.7% per patient-year). VTE that occurs during a medical illness has an intermediate risk of recurrence (4.5% per patient-year) [188]. Therefore,
indefinite therapy is often considered for patients with unprovoked VTE whereas patients with surgically provoked events discontinue anticoagulation after 3 to 6 months of therapy once they have recovered from their surgery and any attendant complications. Patients who develop VTE in conjunction with a medical illness continue anticoagulation for an intermediate duration that generally is continued until the inciting medical illness has been treated into remission or at least 3 months whichever is longer [189].

The presence of thrombophilia does not automatically indicate the need for long-term therapy although indefinite therapy is often considered for patients with known high-risk thrombophilia (e.g., deficiency of AT, PC, or PS, antiphospholipid syndrome, homozygous FVL or prothrombin gene mutation or compound heterozygosity of FVL, and the prothrombin gene mutation). Cancer patients who develop VTE are treated with anticoagulation as long as their cancer remains active or under therapy [189].

Complications of Anticoagulation

The principal complication of anticoagulation is major bleeding. A pooled analysis of 11 clinical trials involving approximately 15,000 patients treated with either UFH or LMWH reported the frequency of major bleeding at 1.9% and 1.1% and a fatal hemorrhage rate of 0.2% and 0.1%, respectively [190]. Given the wide use of anticoagulants for the prevention of thromboembolism in ambulatory and hospitalized patients, bleeding complications related to anticoagulants are likely to be treated by clinicians working in critical care environments.

Reversal of antithrombotic agents is addressed in Chapter 93. A few reversal agents in development, however, deserve special mention. Idarucizumab, a humanized mouse monoclonal antibody directed against dabigatran, has been evaluated clinically for reversal of dabigatran in patients with life-threatening bleeding or in need of an emergent invasive procedure. When administered as a 5-g IV bolus, idarucizumab rapidly reversed dabigatran’s anticoagulant activity, and its effects lasted 12 to 24 hours after administration [191].

Andexanet alfa is a genetically engineered form of factor Xa that binds and inactivates direct and indirect factor Xa inhibitors. Following a bolus and IV infusion, it reduced rivaroxaban and apixaban levels by 90% [192]. FDA approval is expected in 2016. PER977, a small molecule cationic inhibitor that binds to direct oral anticoagulants as well as UFH and LMWH has been shown to reverse the anticoagulant effects of edoxaban in normal volunteers [193]. Once approved, these reversal agents are likely to be invaluable in the treatment of patients with bleeding complications associated with direct oral anticoagulants as well
Utility of Ultrasonography for Evaluation of Venous Thromboembolism

Utility of Ultrasonography for Diagnosis of Deep Vein Thrombosis

Ultrasonography is the primary imaging modality used for the diagnosis of DVT. With appropriate training, intensivists and emergency medicine physicians can perform compression studies with results that are as accurate as those performed by consultative radiology or vascular services; where there is often delay in performance of the examination [194–196]. The frontline intensivist who performs the DVT study accrues major advantage: the examination is done immediately at point of care, it can be repeated as often as required, and it provides important clinical information that is promptly integrated into management plan [194]. The intensivist who is competent in the two-dimensional (2-D) compression examination can perform the examination in a few minutes. The addition of Doppler to the examination (duplex and triplex) affords no improvement in accuracy over the simpler 2-D compression ultrasound test [197]. Proficiency in the 2-D compression examination for DVT is, therefore, a key part of competence in critical care ultrasonography.

Equipment Requirements

The 2-D compression examination is performed with a linear vascular probe (7.5 MHz) of the type that is used to guide vascular access. Lower frequency probes used for cardiac, thoracic, and abdominal scanning do not usually have adequate resolution to examine for venous thrombosis. The width of the scanning field of a linear vascular probe varies according to probe design. The choice of a narrow or wide width is determined by operator preference.

Scanning Technique

Scanning technique is standard regardless of the vessel under examination. The target vein is scanned in its transverse axis. The examiner positions the transducer over the target vessel perpendicular to
the skin surface, and the vessel is centered beneath the transducer by adjusting the position of the transducer. Depth and gain are set for optimal image quality. By standard convention, the orientation marker is set on the right side of the screen, and the probe marker is always directed to the right side of the patient. The vessel is examined for visible thrombus. If no thrombus is visible, an isoechoic thrombus may be present. To examine for this possibility, the transducer is pressed into the skin with the force vector perpendicular to the vein. The amount of applied force is sufficient to deform the adjacent artery. Normal veins are fully compressible with moderate pressure applied with the transducer; such that, with compression, the visible lumen disappears as the opposing venous walls come into full contact (Video 92.1). Thrombus will prevent full compression of the vein. Frequently, the thrombus will only become visible with the compression maneuver. Although the compression maneuver is best performed with transverse view of the vein, the longitudinal view may be used to supplement to examination.

Examination for Deep Vein Thrombosis of the Lower Extremity

The patient is in supine position with the leg externally rotated. The examination proceeds in a proximal to distal direction using an imaging sequence that requires identification and compression at defined anatomic levels of the venous system (Video 92.2) (Fig. 92.3) The mandatory image sequence is as follows:
1. Identification and compression of the proximal common femoral vein (CFV) and its paired artery. In slender individuals, it may be possible to image the distal iliac vein. The CFV is medial to the common femoral artery (CFA).

2. Identification and compression of the junction of the saphenous vein and the CFV. This is common site for thrombus formation.

3. Identification and compression of the CFV at the level of the bifurcation of the CFA into the femoral artery (FA) and profunda femoris artery. There is often a lateral perforating vein that runs between the FA and profunda femoris artery.

4. Identification and compression at the level of the junction of the CFV and the profunda femoris vein. Below this point, the CFV becomes the femoral vein (FV). (The FV may be referred to as the superficial FV. This is confusing; it is actually a deep vein).

5. Identification and compression of the FV. The FV is posterior to the FA. It is very uncommon to find a DVT in the FV in the absence of thrombus at the inguinal level, so there is debate as to how far down the thigh to continue the examination and compression of the SV. However, it does take much time to examine the FV at several points.
5. Identification and compression of the popliteal vein (PV). The knee is flexed with the leg externally rotated, and the probe is placed in the popliteal fossa in order to image and compress the PV. Several points along the PV may be examined. The PV is superficial to the popliteal artery.

Ultrasonography Findings

An intraluminal mass within the vein is diagnostic of thrombus because of the absence of compressibility of the vessel (Video 92.3). Isoechoic thrombus (i.e., noncompressible vessel) suggests that the clot is new. Older clots are echoic. Freely moving thrombus implies instability with risk of dislodgement and resulting PE. As the thrombus ages, it becomes incorporated into the vessel wall, progressively more echoic, and may eventually calcify. An intraluminal mass within the IVC may be thrombus, but intravascular spread of malignancy is a consideration. Renal cell carcinoma is frequently the culprit tumor in this situation.

Examination for Deep Vein Thrombosis of the Upper Extremity

The patient is in supine position with the arm abducted and externally rotated. Starting at the antecubital fossa, the brachial artery is identified in its transverse axis at the cubital fossa. This allows identification of the accompanying brachial veins that are usually paired. The transducer is moved proximally along the brachial veins with examination for visible thrombus followed by compression at multiple points along the medial arm. The paired brachial veins unite to become the axillary vein in the proximal upper arm. The examination continues as far into axilla as possible. Using similar technique, ultrasonography visualization of the superficial veins of the arm is useful in order to assess for thrombus formation associated with IV access (Video 92.4).

Ultrasonography Examination for Deep Vein Thrombosis of the Great Vessels

The internal jugular vein is imaged in its transverse axis and examined for visible thrombus, followed by compression study along its length (Video 92.5). This is a standard part of assessment in preparation for
central venous access.

The subclavian vein (SCV) is imaged in its transverse axis and examined for visible thrombus, followed by compression study along its length (Video 92.6). To locate the vessel, the transducer is held in longitudinal orientation and placed on the clavicle using a sagittal scanning plane directed through the medial third of the clavicle. The transducer is then moved laterally on the clavicle until the SCV appears from underneath the clavicle. With further lateral movement of the probe, the target vessel and its paired artery are visualized in the subpectoral area away from the clavicle. The subclavian becomes the axillary vein when it crosses the lateral part of the first rib. Although visible thrombus is diagnostic, the SCV may be difficult to compress so that absence of compression does not indicate that there is thrombus in the vessel. Difficulty with compressing the vein occurs in obese or muscular patients. If the SCV is fully compressible along its course, no thrombus is present. The absence of compression may be because of patient-specific factors or owing to the presence of an isoechoic thrombus.

The IVC is imaged in its transverse axis and examined for visible thrombus (Video 92.7). A transhepatic approach is used to image the proximal IVC. The longitudinal axis view may also be used. Bowel gas may degrade image quality when attempting to scan the distal IVC, and patient-specific factors such as obesity, anasarca, or heavy musculature limit visualization as well. If the IVC is visible in its extrahepatic course, a compression maneuver is performed. This is may only be possible in slender individuals. In its intrahepatic course, the IVC is not compressible. The proximal superior vena cava (SVC) may be imaged using transesophageal echocardiography. The midesophageal bicaval view can detect an SVC thrombus. This may be associated with CVC.

Limitations

1. Training is required for the intensivist to be competent in the examination for DVT. The anatomic basis for the examination is a key component of the examination because it is mastery of machine control and image acquisition. An overgained image may give the false impression of a thrombus, whereas an undergained image may cause the operator to miss a thrombus. Misorientation of the image may cause confusion between the artery and the vein.

2. Off-axis force application during the compression maneuver may give the false impression that the vein is not compressible. The compression is performed in a direction straight down onto the vessel.
There is concern that a compression of a vein with thrombus carries the risk of dislodgement with resultant PE. This has been reported as a very rare complication of the examination. The definitive identification of a thrombus on the 2-D examination does not require compression for verification of a venous thrombosis.

If the operator exerts too much pressure on the probe while trying to locate a vessel, the vein may not be visible because it is inadvertently compressed. This is common error at the junction of the CFV and the saphenous vein, as well when examining the PV.

When compressing the PV, the probe often slips to one side so the correct image is lost. An alternative method of performing compression of the PV is to center the target vessel on the screen and then apply counterpressure to the overlying patella instead of direct pressure with the probe.

The results of the intensivist examination may be not diagnostic. This occurs when patient-specific factors degrade image quality. Expert-level radiology or vascular service consultation is then necessary.

Lymph nodes, particularly in the inguinal area, may be mistaken for intraluminal thrombus. The distinction is made visualizing the structure in both transverse and sagittal planes. The lymph node will not elongate as will the vein in sagittal scanning plane.

Internal echoes (“smoke”) are frequently encountered in patent veins in the presence of low-flow states. This should not be confused with true thrombi. Venous valves may be mistaken for thrombi. Valves are thin linear echogenic structures that have respirophasic movement and are within a compressible vessel.

Minor anatomic variants are common, particularly with leg veins. For example, the FV may be lateral or medial to the FA instead of posterior to the artery. The profunda femoris vein may be difficult to identify because its junction with the CFV is not at a constant level in the upper thigh.

The results of the examination require documentation. One simple method is to obtain an adequate view at the appropriate anatomic level. The operator then activates the video clip function of the machine with a preset of 4-second duration. The compression maneuver is performed during this period. Each anatomic point is documented in similar manner.

The standard DVT examination does not include the lower leg or lower arm. Although the venous system of these areas can be examined, it requires specific training and adds considerable time to the
examination, particularly for the calf veins. In addition, the finding of DVT in calf or forearm veins has uncertain value for management of the acutely ill patient. Radiology or vascular consultative services have the expertise required for this type of examination.

Echocardiography for Evaluation of Pulmonary Embolism

The main utility of ultrasonography for evaluation of PE derives from its use for diagnosis of DVT. The finding of a DVT is strong evidence that the patient has a PE, given the appropriate clinical circumstance. For this reason, the initial imaging study for patients with suspicion of PE is an immediate DVT study. If this is negative, further imaging such as CT pulmonary angiogram (CTPA) or (V/Q) scan may then be considered. The intensivist who is competent in critical care ultrasonography has, by definition, the ability to perform the DVT study immediately at point of care.

Critical care echocardiography has several applications for the diagnosis and management of PE.

1. Although uncommon, transthoracic echocardiography (TTE) may detect a thrombus in transit through the heart or in the main pulmonary artery [198]. Direct observation of the thrombus is diagnostic and allows the team to take immediate life-saving action, because a visible intracardiac thrombus is often associated with severe hemodynamic failure (Video 92.9). The right apical four-chamber view, subcostal long-axis view, and RV inflow view are useful for identification of a thrombus in transit. Rarely, a PE may be visualized in the main pulmonary artery with TTE from the parasternal short-axis view of the pulmonary artery or from the subcostal short-axis view. A PE may be visualized using transesophageal echocardiography in the main and right pulmonary arteries but not often in the left pulmonary artery on account of tracheal air shadowing [199] (Video 92.9).

2. PE is always a consideration for the patient with hemodynamic failure. Goal-directed echocardiography (GDE) is useful in identification of cardiac dysfunction that is consistent with modynamically significant PE. The occurrence of hemodynamic failure from the RV afterload effect of PE is strongly associated with RV dilatation [200]. The patient who is in shock from PE has characteristic features on GDE that are consistent with acute cor pulmonale (APE) (Video 92.10).

a. Parasternal long-axis view: The findings include a rounded and dilated RV outflow tract and paradoxic septal movement (typically,
an end-systolic posterior movement of the interventricular septum).

b. Parasternal short-axis view: The findings include flattening of interventricular septum, dilation of the RV, and paradoxical septal movement (typically, an end-systolic movement of the interventricular septum toward the LV cavity).

c. Apical four-chamber view: The RV to LV size ratio is greater than 1. A ratio that is greater than 1 is consistent with APE. Submassive PE may be associated with moderate RV dilation (RV to LV size ratio >0.6).

d. Subcostal long-axis view: The RV to LV size ratio is greater than 1.

e. IVC long-axis view: The IVC is dilated.

The intensivist who is competent in advanced critical care echocardiography utilizes Doppler based measurements of RV function that are relevant to assessment of the PE, such as pulmonary artery pressures, tissue Doppler tricuspid annular velocity, tricuspid annular planar systolic excursion, respirophasic variation of pulmonary artery stroke volume, reduced main pulmonary artery acceleration time, and biphasic systolic velocity time interval of the pulmonary outflow in the proximal pulmonary artery. All of the TEE views described above have equivalent views that may be obtained with TEE.

Except for the unusual circumstance where the PE is directly visualized by echocardiography, the echocardiography examination is mainly useful to support the diagnosis of PE and to aid in categorizing the severity. In the acute situation where the patient presents with an undifferentiated shock state, GDE is useful because it may identify a dilated RV or APE, which, absent other explanation, immediately suggests the possibility of a hemodynamically consequential PE. This directs the care team to obtain further confirmatory studies. GDE is helpful for categorization of submassive PE, and, through serial examinations, it can is used to follow response to therapy. The GDE examination is considered within the context of the entire clinical picture, and is combined with other aspect of critical care ultrasonography such as DVT study and lung ultrasonography. There are other causes of RV dysfunction other than PE, and the patient may have alternative or coexisting diagnosis that will complicate the management of PE. Echocardiography cannot be used to exclude PE because the echocardiography results may be normal if the clot burden is low.

The combination of echocardiography, thoracic ultrasonography, and
DVT study may be useful to reduce the need for unnecessary CTPA, when there is clinical suspicion for PE. Koenig et al. have reported that the finding of negative DVT study, absence of RV dilation, and the finding of an alternative diagnosis with ultrasonography for the clinical presentation (e.g., lung or cardiac abnormality) predicted that the patient would have a negative CTPA [201]. Nazerian et al. reported similar results with the addition of comprehensive lung ultrasonography [202]. Multisystem ultrasonography in combination with clinical scoring systems and d-dimer results may be useful in reducing the rate of negative CTPA, although it is clear that some patients will still require CTPA when ultrasonography results are equivocal. Mathis et al. reported that pulmonary emboli commonly result in small areas of consolidation immediately deep to the pleural interface with preferential distribution to the lower lobes of the lung [203]. This is a difficult area to image in the critically ill patient who is generally in supine position, so their results have uncertain application for the intensivist.

7. PREPIC Study Group: Eight-year follow-up of patients with permanent

INTRODUCTION

Thromboembolic disease is commonly encountered among critically ill patients [1]. While these patients are at high risk for developing arterial and venous thrombosis due to underlying comorbidities, central venous catheter placement, and immobility, they are also at high risk for hemorrhagic complications resulting from gastrointestinal stress ulcerations, invasive procedures, liver dysfunction, uremia, or coagulopathy [2]. These divergent features often complicate antithrombotic treatments for the prevention or management of thrombosis. Limitations in administration routes, hemodynamic instability, alterations in renal and hepatic function, and drug interactions further complicate the administration of these high-risk medications [3].

This chapter focuses on the mechanisms of action, pharmacokinetics, pharmacodynamics, clinical indications, complications of therapy, and reversal options for antithrombotic pharmacotherapy in critically ill patients.
Overview of Antiplatelet Pharmacotherapy

Antiplatelet agents target mechanisms in platelet activation, adhesion, and aggregation. Pharmacological inhibitors of platelet function fall into five general categories: thromboxane (TXA) inhibitors, antagonists of adenosine diphosphate (ADP)-mediated platelet activation, glycoprotein (GP) IIb/IIIa complex inhibitors, thrombin receptor antagonists, and phosphodiesterase inhibitors (Fig. 93.1).

**FIGURE 93.1** Platelet activation and pharmacological inhibitors of platelet function. Platelet activation involves four mechanisms: adhesion to sites of vascular injury, release of stimulatory compounds, aggregation, and priming of coagulation. Pharmacological inhibitors of platelet function target adhesion, release, and aggregation mechanisms. Platelet adhesion is a four-step process involving tethering of von Willebrand factor (VWF) to glycoprotein (GP) IIb platelet receptors, a potential target of investigational agents. The rolling phase of adhesion involves interaction between vascular collagen with GP VI and GP Ia/IIa receptors, another potential target of investigational agents. The activation phase of adhesion involves release of thromboxane A2 (TXA2) and adenosine diphosphate (ADP) which can be blocked with use of aspirin, P2Y12 inhibitors, and thromboxane (TR) receptor antagonists. The stable adhesion phase involves the interaction of GP IIb/IIIa receptors with fibrinogen and
VWF, which can be blocked with the use of GP IIb/IIIa inhibitors. Thrombin receptor antagonists block platelet aggregation by selectively blocking PAR-1 thrombin receptors.

Antiplatelet ‘resistance’ and ‘nonresponse’ are terms applied to clinical outcomes characterized by failure to prevent a thrombotic event due to inadequate platelet inhibition [4]. Resistance is conferred by underlying clinical, cellular, and genetic mechanisms. It is best confirmed by platelet function testing [4]. While several methods are available for measuring the overall and drug-specific platelet aggregation, standard testing protocols have yet to be established [5].

Aspirin and Aspirin Derivatives

Pharmacology, Pharmacodynamics, and Monitoring

Aspirin, or acetylsalicylic acid, is a prodrug of salicylic acid that blocks platelet activation. Aspirin irreversibly inhibits cyclooxygenase enzymes (COX-1, COX-2), reducing prostaglandin and TXA by-products generated from arachidonic acid. Thromboxane A₂ stimulates platelet activation, aggregation, and recruitment [6]. COX-1 enzymes are present in most tissues, but larger amounts are found in the stomach, kidneys, and platelets. The prostaglandin products of COX enzyme activity provide protection from gastrointestinal mucosal injury. COX-2 is found in both nucleated and nonnucleated cells and is responsive to inflammatory stimuli. Inhibition of COX-1 appears to be the primary mechanism by which aspirin inhibits hemostasis. Aspirin’s acetylation of platelet COX-1 enzymes causes inhibition of platelet TXA₂ production. The irreversible antiplatelet effect lasts for the lifespan of the platelet (7 to 10 days). Saturation of aspirin’s antithrombotic mechanisms occurs at doses as low as 30 mg with larger doses (>3,000 mg daily) required to inhibit COX-2 and produce systemic anti-inflammatory effects. Consequently, there is a 50- to 100-fold variation between the daily doses required to suppress inflammation and inhibit platelet function [7].

Enteric-coated and delayed release formulations have diminished bioavailability, take 3 to 4 hours to reach peak plasma levels, and have delayed onset. Rectally administered aspirin has variable absorption with a bioavailability of 20% to 60% over a 2- to 5-hour retention time [8]. For acute thrombosis, immediate-release enteral aspirin is preferred [9].

The optimal aspirin dose that maximizes efficacy and minimizes toxicity is controversial. Evidence-based recommendations vary from 75 to 325 mg daily. There are currently no data suggesting inferiority of lower (75 to 100 mg) to higher (>100 mg) maintenance dosing in
preventing thromboembolic events [9,10].

Recurrent vascular thrombotic episodes despite aspirin therapy occur at rates between 2% and 6% of patients per year [11] Aspirin resistance occurs in 5.5% to 45% of aspirin-treated patients. Possible mechanisms of aspirin resistance include extrinsic factors (adherence, absorption, dosage formulation, and smoking) and intrinsic factors (pharmacodynamic alterations, receptor polymorphisms, up regulation of nontargeted platelet activation pathways). In clinical trials, aspirin resistance has been associated with an increased risk of death, acute coronary syndromes (ACS), and stroke [12].

Clinical Indications

Aspirin is indicated for the primary and secondary prevention of arterial and venous thrombosis (Table 93.1). Aspirin is effective in reducing atherothrombotic disease morbidity and mortality in ACS, stable angina, coronary bypass surgery, peripheral arterial disease (PAD), transient ischemic attack, acute ischemic stroke, and polycythemia vera. Aspirin provides effective thromboprophylaxis in patients on warfarin with prosthetic heart valves and in patients with nonvalvular atrial fibrillation [13].

Complications and Reversal of Effect

Aspirin increases the incidence of major, gastrointestinal, and intracranial bleeding [6]. The recommended interval for discontinuation of aspirin prior to elective surgery or procedures is 7 to 10 days. Therapy can be resumed approximately 24 hours or the next morning after surgery when there is adequate hemostasis [14]. For patients exhibiting clinically significant bleeding or requiring emergent surgery, platelet transfusion may be warranted (Table 93.2). Intravenous desmopressin antagonizes aspirin’s effect, suggesting a role in emergent situations as well [15].

**P2Y₁₂ Inhibitors**

Platelet transfusion and/or desmopressin
0.3–0.4 mcg/kg IV bolus

specialist in select patient care scenarios (i.e., recent placement of drug eluting stent)

**Warfarin**

INR 4–10 (no signs of bleeding)
- Vitamin K; 1–2.5 mg by mouth

INR >10 (no signs of bleeding)
- Vitamin K; 2.5–5 mg by mouth

Surgery within 24 h:
- Interrupt warfarin
- Vitamin K 2.5–5 mg IV

Surgery within 48 h:
- Interrupt warfarin
- Vitamin K 2.5 mg orally

Urgent surgery or invasive procedure:
- Four-factor PCC (Kcentra)
- Vitamin K 10 mg IV

Severe or life-threatening bleed:
- Interrupt warfarin therapy
- Vitamin K 10 mg IV + FFP 15–30 mL/kg
- Four-factor PCC (Kcentra)
  - INR <4 = 25 units/kg
  - INR 4–6 = 35 units/kg
  - INR >6 = 50 units/kg
  - Maximum dosing weight = 100 kg
- Consider administering three-factor PCC 25–50 units/kg (product specific dosing) if four factor unavailable or rVIIa 10-90

- Close monitoring of INR is needed for patients demonstrating elevations in INR on warfarin therapy and to assess need for supplemental vitamin K
- Repeat testing of the INR at 24 h and pre-operation may be needed to assess need for supplemental vitamin K or FFP
- IV and oral therapy are preferred over subcutaneous administration due to erratic absorption
- PCCs and rVIIa have been associated with thromboembolic events
mcg/kg IV (if no PCC available) as alternative or adjunct therapy

Indirect Factor Xa Inhibitors<sup>a</sup>
(Fondaparinux)

- Interrupt fondaparinux
- rVIIa 90 mcg/kg IV<sup>b,c</sup>
- Prothrombin complex concentrates
  - FEIBA 20–50 units/kg IV<sup>b,c</sup>
  - Kcentra 25–50 units/kg IV<sup>b,c</sup>

Duration of effect is dependent upon renal function/clearance and can range from 13 to 21 h in healthy persons, and be prolonged in renal dysfunction

- PCCs and rVIIa have been associated with thromboembolic events
- FEIBA is derived from human plasma, thus risk of immune-mediated reaction and infection transmission

Direct Factor Xa inhibitors<sup>a</sup>
(Apixaban, Betrixaban, Edoxaban, and Rivaroxaban)

Direct thrombin inhibitors<sup>a</sup>

- Interrupt therapy
- rVIIa 90 mcg/kg IV<sup>b,c</sup>
- Prothrombin complex concentrates
  - FEIBA 50—100 units/kg IV<sup>b,c</sup>
  - Kcentra 50 units/kg<sup>b,c</sup>

Duration of effect is dependent upon renal function/clearance and hepatic function, and can be prolonged in organ dysfunction

- PCCs and rVIIa have been associated with thromboembolic events
- FEIBA is derived from human plasma, thus risk of immune-mediated reaction and infection transmission

- Hemofiltration and hemodialysis may be effective in the removal of bivalirudin and dabigatran
- Desmopressin 0.3–0.4 mcg/kg IV bolus<sup>c</sup>
- Prothrombin complex concentrates
  - FEIBA 50–100 units/kg IV<sup>b,c</sup>

---

<sup>a</sup>No specific antidote exists; beneficial effects described in the literature limited to animal models,
Aspirin produces gastrointestinal ulcerations and hemorrhage through direct irritation of the gastric mucosa and via inhibition of prostaglandin synthesis. Aspirin, in recommended doses, increases the risk of gastrointestinal bleeding 1.5- to 3-fold \[16\]. Enteric-coated and buffered aspirin doses ≤325 mg do not reduce the incidence of gastrointestinal bleeding \[17\]. Aspirin-induced gastric toxicity can be prevented with concurrent use of acid-suppressive therapy \[16\].

Underlying aspirin allergy can exacerbate respiratory tract disease, angioedema, urticaria, or anaphylaxis and is estimated to occur in 10% of the general population. These patients may be converted to alternative antiplatelet therapies. Leukotriene-modifying agents may reduce aspirin-provoked respiratory reactions but do not eliminate the risk. For patients with a compelling indication for therapy, aspirin desensitization may be considered \[18\].

P2Y\textsubscript{12} Inhibitors

Pharmacology, Pharmacodynamics, and Monitoring

P2Y\textsubscript{12} inhibitors prevent platelet activation by blocking adenosine diphosphate (ADP) binding to P2Y\textsubscript{12} receptors. This action prevents activation of the GP IIb/IIIa receptor complex on the platelet surface \[9\]. Thienopyridine derivatives, clopidogrel, prasugrel, and ticlopidine, are prodrugs requiring hepatic activation via the cytochrome P450 (CYP450) isoenzyme system (Table 93.3). Metabolism by CYP450 plays a key role in the onset of action, potency, and drug interaction profile of these agents \[19,20\]. A loading dose provides a rapid increase in plasma concentration and a faster onset of action. Both clopidogrel and ticlopidine require a two-step activation process via CYP450. Prasugrel undergoes one-step oxidation by multiple CYP450 isoenzyme pathways which are believed to be responsible for its more predictable action.

IV, intravenous; CYP, cytochrome P; LD, loading dose.

While thienopyridine metabolites have a short plasma elimination half-life (1 to 8 hours), their irreversible activity at P2Y\textsubscript{12} receptors spans the life of the platelet (7 to 10 days). The onset of action, duration of antiplatelet effect, and unpredictable levels of platelet inhibition led to the development of newer agents [21]. Ticagrelor is a nonthienopyridine P2Y\textsubscript{12} inhibitor that does not require hepatic activation resulting in immediate, short-acting, dose-dependent inhibition of platelet activation aggregation [22]. Ticagrelor binds reversibly at P2Y\textsubscript{12} receptors resulting in a shorter duration of antiplatelet activity compared to thienopyridines [22]. Cangrelor in an intravenous (IV) agent with a very short half-life and rapid onset that lends itself useful in the procedural setting [23].

Resistance to clopidogrel occurs in 4% to 34% of patients and depends on the agent, type, and timing of platelet function test, as well as underlying comorbidities such as diabetes and obesity [20]. Possible
mechanisms of P2Y<sub>12</sub> inhibitor resistance include extrinsic factors and intrinsic factors. Recent literature highlighted the importance of genetic and drug-induced alterations of CYP3A4 enzymes, the pathway responsible for thienopyridine activation [21]. Clopidogrel resistance has been associated with an increased risk of death, myocardial infarction (MI), and stroke. Monitoring the antiplatelet effect of P2Y<sub>12</sub> inhibitors using platelet function testing is an evolving area of research [5]. While the high incidence of varied responses to thienopyridines due to CYP450 polymorphisms and potential drug interactions has suggested a strategy for improving response, the routine use of point-of-care platelet function testing has not been established [24]. Recent literature does not show significant improvements in clinical outcomes with platelet-function monitoring and treatment adjustment for coronary stenting, as compared with standard antiplatelet therapy without monitoring [24]. For patients with threatened in-stent thrombosis and presumed or confirmed clopidogrel resistance, maintenance dosing up to 150 mg daily could be attempted with platelet function testing. Higher maintenance dosing has not shown to improve antiplatelet activity in all patients with established CYP450 polymorphisms [5,10]. In patients with an acute coronary syndrome who were referred for an invasive strategy, there was no significant difference between a 7-day, double-dose clopidogrel regimen and the standard-dose regimen, or between higher-dose aspirin and lower-dose aspirin, with respect to the primary outcome of cardiovascular death, MI, or stroke [10]. Availability of newer agents and unavailability of platelet function testing capacity make switching to agents such as prasugrel and ticagrelor with less pharmacokinetic variability more practical.

Clinical Indications

P2Y<sub>12</sub> inhibitors are indicated for primary and secondary thrombosis prevention in a variety of disease states (Table 93.4). Ticlopidine reduces thrombotic events in patients with stroke, but is associated with neutropenia, thrombocytopenia, and thrombotic thrombocytopenic purpura [21]. Clopidogrel is indicated alone or in combination with aspirin for primary and secondary prevention of ischemic events in ACS, PAD, stroke, and coronary artery disease. Prasugrel is indicated alone or in combination with aspirin for the prevention of thrombotic cardiovascular events, including in-stent thrombosis, in ACS patients who are managed with percutaneous coronary intervention (PCI) [20].
Ticagrelor is indicated in combination with aspirin for primary and secondary prevention of ischemic events in patients experiencing ACS. Ticagrelor may be used in preference to clopidogrel in NSTEMI patients (or ACS) patients undergoing early invasive reperfusion procedures [25]. Cangrelor is indicated for the reduction of cardiovascular (CV) events in select patients undergoing PCI [26].

Complications and Reversal of Effect

The incidence of major bleeding with P2Y₁₂ inhibitors varies between agents, dosing, patient populations, and concomitant antithrombotic therapies. Gastrointestinal hemorrhage is a common complication of
P2Y\textsubscript{12} inhibitor therapy [16]. For patients exhibiting clinically significant bleeding, platelet transfusion may be warranted in combination with IV desmopressin (Table 93.2) [15]. P2Y\textsubscript{12} inhibitors should be avoided in patients undergoing neuraxial analgesia due to the risk of subdural hematoma [27]. Therapy should be discontinued 7 to 10 days prior to elective surgery or invasive procedure and resumed approximately 24 hours or the next morning after surgery.

Due to the unique structure of ticagrelor, it has been associated with adverse effects not seen with thienopyridine derivatives. An increased rate of dyspnea, ventricular pauses, and hyperuricemia has been reported with ticagrelor in clinical trials likely due to its capacity to delay adenosine metabolism [22].

### Glycoprotein IIb/IIIa Inhibitors

**Pharmacology, Pharmacodynamics, and Monitoring**

GP IIb/IIIa receptors are expressed on the platelet surface, with approximately 50,000 to 80,000 copies per platelet. Blocking GP IIb/IIIa receptors prevents platelet activation, aggregation, and fibrinogen-mediated platelet-to-platelet bridging. Intravenous GP IIb/IIIa inhibitors (abciximab, eptifibatide, and tirofiban) vary in their structure and pharmacokinetic properties (Table 93.5) [9,28].

CrCl; creatinine clearance using Cockcroft–Gault equation.

Although the exact threshold required for efficacy with these agents has not been established, >80% platelet inhibition is thought to be a target associated with adequate antiplatelet activity in patients with ACS and in those undergoing PCI [29]. Abciximab is a human–murine chimeric monoclonal antibody that demonstrates a dose-dependent inhibition of GP IIb/IIIa receptors. After an initial intravenous bolus and infusion, the onset of platelet inhibition is rapid (5 minutes) and 80% to 90% of ADP-induced platelet aggregation is suppressed [28,29]. Abciximab has a strong affinity for the receptor, resulting in occupancy that persists for weeks. Once discontinued, platelet function recovers gradually, with bleeding time normalizing at 12 hours and ADP-induced aggregation returning at 24 to 48 hours [28,29].

Both eptifibatide, a synthetic peptide, and tirofiban, a synthetic small molecule, demonstrate high selectivity, but reduced affinity for the GP IIb/IIIa receptor when compared to abciximab; both exhibit platelet inhibition that is linear and dose dependent. An intravenous eptifibatide or tirofiban bolus dose followed by an infusion provides >80% inhibition of ADP-induced platelet aggregation. For patients undergoing PCI, a second eptifibatide bolus 10 minutes after the initial dose further enhances platelet inhibition at 1 hour. Since both agents dissociate from the GP IIb/IIIa receptor rapidly, normal platelet aggregation is restored within 4 to 8 hours after drug discontinuation [28,29]. Platelet counts should be monitored within the first 24 hours while taking GP IIb/IIIa inhibitors. For abciximab, platelet counts should be evaluated within 2 to 4 hours of initiation due to a higher risk of thrombocytopenia.

Clinical Indication

GP IIb/IIIa inhibitors are included in evidence-based guidelines as adjunctive therapy for patients with ACS and those undergoing PCI (Table 93.6). Optimal use of GP IIb/IIIa inhibitors involves appropriate
patient risk stratification, use with other antithrombotic agents, appropriate dose, and duration of therapy [25,29].

Abnormal bleeding within the previous 30 d or a history of bleeding diathesis

Concomitant or planned administration of other parenteral glycoprotein IIb/IIIa inhibitors

Hypersensitivity to active ingredient or any other product component

Hypersensitivity to murine proteins (abciximab)

Major surgery (within the previous 6 wk)

Stroke (within previous 30 d)

Severe hypertension (systolic pressure over 180–200 mm Hg or diastolic pressure above 110 mm Hg)

History or clinical suspicion of intracranial bleeding, tumor, arteriovenous malformation, or aneurysm

Pericarditis

Aortic dissection

Thrombocytopenia following prior tirofiban administration

Renal impairment:
CrCl <50 mL/min, 180 mcg/kg actual body weight (maximum 22.6 mg) IV bolus as soon as possible, followed by 1 mcg/kg/min (maximum 7.5 mg/h) infusion

LD: 25 mcg/kg IV within 5 minutes and then 0.15 mcg/kg/min for up to 18 h.

Renal impairment:
CrCl ≤60 mL/min, give LD 25 mcg/kg within 5 minutes and then 0.075 mcg/kg/min for up to 18 h.

ACS, acute coronary syndromes; CABG, coronary artery bypass graft; CrCl, creatinine clearance; LD, loading dose; MI, myocardial infarction; PCI, percutaneous coronary intervention; UA, unstable angina.

Complications and Reversal of Effect

The frequency of major bleeding with GP IIb/IIIa therapy ranges from 1% to 14% of patients and depends on the agent, concomitant therapies, and settings of ACS or PCI [28,29]. Failure to adjust dosing in renal dysfunction further increases the risk of bleeding [30]. Factors associated with bleeding risk include age, female gender, body weight, diabetes, congestive heart failure, renal function, concomitant fibrinolytic use,
prolonged femoral sheath placement, and heparin dosing [29,31,32].

The duration of the antiplatelet effect is agent specific and is influenced by platelet binding (abciximab binds to platelets for up to 10 days) and renal function (tirofiban and eptifibatide have half-lives of 1.5 to 3 hours with normal renal function). An intravenous desmopressin bolus of 0.3 μg per kg may be beneficial in reducing bleeding time (Table 93.2) [33].

Nonhemorrhagic side effects of GP IIb/IIIa inhibitors include severe thrombocytopenia. The incidence of thrombocytopenia with eptifibatide and tirofiban is similar to placebo, with rates ranging from 0.2% to 0.3% of treated patients. With abciximab, the incidence is reported as 5%; however, up to 4% of cases can be due to pseudothrombocytopenia as a result of platelet clumping. The onset of thrombocytopenia usually occurs within the first 24 hours of infusion, but delayed onset has been reported [34].

Platelet or red blood cell transfusions may be warranted for patients with persistent thrombocytopenia or clinically significant bleeding and must take into account drug concentrations in the plasma or drug bound to platelets [28]. Abciximab has been associated with antibody formation in 6% of patients. The risk of thrombocytopenia and immune-mediated reactions may limit repeat use [9,34]. GP IIb/IIIa inhibitor administration should be avoided in patients requiring neuraxial analgesia due to risk of subdural hematoma [27].

Other Antiplatelet Targets

Pharmacology, Pharmacodynamics, and Monitoring

While aspirin, P2Y12 receptor antagonists, and GP IIb/IIIa inhibitors are the predominant targets of antiplatelet pharmacotherapy, several other targets with varying degrees of potency are available. Vorapaxar is a thrombin receptor (protease-activated receptor-1) antagonist that inhibits thrombin-mediated and thrombin receptor agonist peptide (TRAP)-mediated platelet aggregation [35]. Other available oral drugs that effect platelet function include cilostazol and dipyridamole. Cilostazol blocks platelet activation via phosphodiesterase 3 (PDE3) inhibition. PDE3 inhibition increases cAMP concentrations resulting in inhibition of platelet aggregation and an increase in vasodilation [36]. Cilostazol is extensively metabolized by the CYP 450-3A4 subclass. Avoidance of therapy or reduced dosing may be required for patients taking potent CYP3A4 inhibitors [37]. Dipyridamole inhibits adenosine binding to platelets and endothelial cells. The increase in adenosine leads to a rise in cyclic adenosine monophosphate (cAMP), which in turn decreases platelet responsiveness to various stimuli. Dipyridamole is metabolized hepatically and has a half-life of approximately 10 hours [9].
Clinical Indications

Vorapaxar is indicated for the reduction of CV events in patients with a MI or PAD [35]. Cilostazol is indicated for treatment of intermittent claudication symptoms and has shown benefit in reducing symptoms and improving walking distance [37]. Dipyridamole is indicated as adjunctive therapy for the prevention of thromboembolism in patients with cardiac valve replacement. Combined with aspirin, dipyridamole is indicated for secondary prevention of cerebrovascular accidents and TIA. The combination of aspirin and extended-release dipyridamole was associated with reductions in major vascular events in patients with stroke or TIA (Table 93.7) [9,38].

CHF, congestive heart failure; LFT, liver function tests; TIA, transient ischemic attack.
Complications and Reversal of Effect

Vorapaxar has a long half-life (165 to 311 hours) with 50% inhibition of platelet aggregation recorded for as long as 4 weeks after discontinuation of therapy [21,35]. Nonhemorrhagic complications of cilostazol therapy include headache, peripheral edema, and tachycardia [37]. While headache is the most common adverse effect associated with dipyridamole therapy, hemorrhage may also occur. For patients exhibiting clinically significant bleeding, platelet transfusion may be warranted.

Overview of Anticoagulant Pharmacotherapy

Blood coagulation has been summarized previously in Chapter 88. Anticoagulant agents inhibit thrombosis and propagation by inhibiting thrombin directly or indirectly by attenuating thrombin generation (Fig. 93.2). Anticoagulants work with traditional agents including warfarin and heparin derivatives. Newer agents such dabigatran, rivaroxaban, apixaban, and edoxaban have a more fined mechanism of action and often referred to as target-specific oral anticoagulants (TSOACs) and direct acting oral anticoagulants (DOACs) [39].

**FIGURE 93.2** The coagulation cascade comprises...
the intrinsic (contact activation) pathway and the extrinsic (tissue factor) pathway. Each pathway generates a series of reactions in which inactive circulating enzymes and their cofactors are activated. These activated factors then catalyze the next reaction in the cascade. Thrombin plays a pivotal role by triggering the conversion of soluble fibrinogen in insoluble fibrin monomers, which serve as the foundation for thrombus formation. Thrombin also activates factors VIII, V, and XIII. Factor XIII generates the covalent bonds that link fibrin strands, ensuring structural integrity. Anticoagulants, either through their interaction with antithrombin, or through a direct inhibition of thrombin, interrupt these enzymatic reactions.

Unfractionated heparin (UFH) and low-molecular-weight heparin (LMWH) are effective in acute thrombosis due to their rapid onset. Since they are dependent on the presence of antithrombin (AT) for clotting factor inhibition, they are considered indirect anticoagulants. Heparins contain a pentasaccharide sequence that binds to AT, producing a conformational change that accelerates AT inactivation of coagulation factors XIIa, IXa, XIa, Xa, and IIa (thrombin). Of these, thrombin and Xa play the most critical role in the coagulation cascade. The active pentasaccharide sequence responsible for catalyzing AT is found on one-third and one-fifth of the chains of UFH and LMWH, respectively. Fondaparinux is a synthetic analog of this naturally occurring pentasaccharide [40].

Unfractionated Heparin

Pharmacology, Pharmacodynamics, and Monitoring

UFH is composed of a heterogeneous mixture of highly sulfated polysaccharide chains that vary in molecular weight, anticoagulant activity, and pharmacokinetic properties. A minimum of 18 saccharide units are required for UFH to form a ternary complex with AT and inhibit thrombin. Once bound to AT molecules, UFH can readily dissociate and bind to other AT molecules. Alternatively, the only requirement for factor Xa inhibition is for the heparin-AT complex to be formed. UFH has equal inhibitory activity against factor Xa and thrombin, binding in a 1:1 ratio. The heparin-AT complex also catalyzes the inhibition of factors such as IXa, XIa and XIIa.

Since UFH is poorly absorbed orally, intravenous or subcutaneous injections are the preferred administration routes [41]. When given as subcutaneous injection with therapeutic intent, UFH doses need to be large enough (>30,000 units per day) to overcome erratic bioavailability.
UFH readily binds to plasma proteins after parenteral administration which contributes to variable anticoagulant response. Despite these limitations, intravenous administration rapidly achieves therapeutic plasma concentrations that can be monitored and adjusted based on infusion rates [42].

UFH clearance from systemic circulation is dose related and occurs through two independent mechanisms [42]. The initial phase is rapid and saturable binding to endothelial cells, macrophages, and local proteins where UFH is depolymerized. The second phase is a slower, nonsaturable, renal-mediated clearance. At therapeutic doses, UFH is cleared primarily in the initial phase with higher-molecular-weight chains being cleared more rapidly than lower-weight counterparts. As elimination becomes dependent on renal clearance, increased or prolonged UFH dosing provides a disproportionate increase in both the intensity and duration of anticoagulant effect. With therapeutic intravenous doses, the half-life of UFH is approximately 60 minutes [41,42].

The anticoagulant response to UFH is monitored using activated partial thromboplastin time (aPTT), a measurement sensitive to the inhibitory effects of thrombin. The aPTT should be measured every 6 hours, and doses adjusted accordingly, until the patient sustains therapeutic levels. Once steady state is reached, the frequency of monitoring can be extended.

Weight-based dosing nomograms are recommended for treatment of thromboembolic disease. Such nomograms have been associated with a shorter time to reach a therapeutic level without an increase in bleeding events. UFH dosing nomograms differ between hospitals due to differences in thromboplastin agents and inter-laboratory standards in aPTT measurements [43].

**Clinical Indications**

Clinical indications for UFH include treatment of ACS, treatment or prevention of venous thromboembolism (VTE), bridge therapy for atrial fibrillation, and cardioversion (Table 93.8) [41,44]. Due to UFH’s short half-life and reversibility, it remains the best option in patients with bleeding risk or organ dysfunction. Patients with fluctuating renal function or a calculated creatinine clearance less than 30 mL per minute are generally not good candidates for LMWH or fondaparinux due to the risk of accumulation and increased bleeding risk, and should be given
UFH [45]. When used for thromboprophylaxis in medical patients, three times daily heparin dosing provides better efficacy in reducing VTE events compared to twice daily dosing, but generates more major, but not minor, bleeding episodes [46].

Contraindications
- Uncontrollable active bleeding, except when due to disseminated intravascular coagulation
- Instances in which blood coagulation tests cannot be performed at necessary intervals
- Severe thrombocytopenia
- Positive test for immune-mediated HIT
- Patients within a remote history of HIT (>100 d) could be considered for a rechallenge with heparin provided a negative antibody test

ACS, acute coronary syndromes; HIT, heparin-induced thrombocytopenia; HITT, heparin-induced thrombocytopenia with thrombosis; LD, loading dose; VTE, venous thromboembolism.
Complications and Reversal of Effect

The major complications of UFH therapy include bleeding (major bleeding, 0% to 7%; fatal bleeding, 0% to 3%), heparin-induced thrombocytopenia (1% to 5%), and osteoporosis (2% to 3% risk of vertebral fracture with less than 1 month of treatment) [47]. Hemorrhagic episodes are associated with anticoagulation intensity, route of administration (continuous infusions are associated with lower rates), and concomitant use of GP IIb/IIIa inhibitors, aspirin or fibrinolytic agents [47].

Patient-specific risk factors for bleeding include age, gender, renal failure, low body weight, and excessive alcohol consumption [47]. Perioperative anticoagulation must be individualized based on the surgery or procedure and the patient’s risks for thrombosis and bleeding. Discontinuing therapeutic doses of heparin 4 hours before surgery and measuring an aPTT is usually sufficient since normal hemostasis is restored in this time frame [14]. Therapeutic-dose UFH therapy can be restarted 12 hours after major surgery, but should be delayed if evidence of bleeding is present. There is no contraindication to neuraxial techniques in patients receiving twice daily, low-dose UFH subcutaneously, as the risk for developing spinal hematoma appears to be minimal [14,27].

Treatment of UFH-related bleeding includes protamine sulfate, transfusion, and supportive care. Protamine sulfate binds to UFH to form a stable salt, which renders UFH inactive. Protamine dosing is dependent on timing of the last UFH dose (Table 93.9) [41,48]. If the dose of UFH is unknown, the maximal tolerated protamine dose of 50 mg can be slowly administered followed by serial measurements of aPTT. Adverse reactions, such as hypotension and bradycardia, are common. However, reaction severity can be reduced by slowly administering protamine over 1 to 3 minutes. Allergic responses to protamine are more common in patients who have been previously exposed to the drug, but patients can be pre-treated with corticosteroids and antihistamines [41,49].

Illustration assumes an 80-kg patient given a bolus and infusion for 3 hours that developed clinically significant bleeding.

<sup>a</sup>Assumes half-life of heparin to be 1 hour

<sup>b</sup>Calculated amounts of heparin remaining at 1 hour following the initiation of continuous infusion may be overestimated in this model

<sup>c</sup>Administer no more than 20 mg of protamine per minute, with a max of 50 mg over any 10 minute period

Low-Molecular-Weight Heparins

Pharmacology, Pharmacodynamics, and Monitoring
LMWHs are derived from UFH by chemical or enzymatic depolymerization, yielding fragments approximately one-third the molecular weight of UFH. All LMWH molecules contain the active pentasaccharides that catalyze AT inhibition of factor Xa. Because of their smaller size, LMWHs have decreased affinity for plasma proteins and cellular binding sites, resulting in a superior pharmacokinetic profile compared to UFH. LMWHs also have increased bioavailability after subcutaneous injection, renal clearance that is dose-independent, and a longer half-life (17 to 21 hours). LMWHs are administered in fixed doses for thromboprophylaxis or in total body weight-adjusted doses for therapeutic anticoagulation (Table 93.10) [41,42].

- Patients within a remote history of HIT (>100 d) could be considered for a rechallenge with heparin provided a negative antibody test

ACS, acute coronary syndromes; CrCl, creatinine clearance; DVT, deep vein thrombosis; HIT, heparin-induced thrombocytopenia; HITT, heparin-induced thrombocytopenia with thrombosis; MI, myocardial infarction; VTE, venous thromboembolism

With their predictable dose response (peak anti-Xa activity occurs 3 to 5 hours after injection), laboratory monitoring is usually not necessary. Anti-Xa monitoring is optional in high-risk patient populations, specifically renal insufficiency, obesity, and pregnancy. In these cases, peak anti-Xa plasma levels are drawn 4 hours after administration, and subsequent doses are adjusted to a target range of 0.5 to 1.1 IU per mL [50]. Trough levels can be assessed to determine clearance in surgical, procedural, and patient bleeding scenarios.

Clinical Indications

LMWHs require fewer injections and produce fewer adverse events compared to subcutaneous UFH. In hospitalized medical patients receiving thromboprophylaxis, LMWH was associated with a lower risk of deep vein thrombosis (DVT), fewer injection-site hematomas, and no difference in bleeding when compared with UFH [51]. LMWHs have largely replaced intravenous UFH in patients with acute VTE who are able to receive unmonitored anticoagulation in the ambulatory setting. UFH remains the preferred option for ACS patients, those who may require an urgent surgical intervention, those with compromised renal function, or those requiring intensive monitoring for other reasons [41].
Recent data suggest reduction in pulmonary embolism (PE) rates with LMWH vs heparin prophylaxis for VTE prophylaxis in the ICU [52].

Complications and Reversal of Effect

Hemorrhage is the major complication of LMWH therapy, with data suggesting lower rates when compared to UFH. Major bleeding is reported to occur in 0% to 3% of patients [41,47]. Periprocedural thromboembolic risk assessment, bleeding risk assessment, and physician preference will play a role in determining whether LMWH prophylaxis is continued or withheld in the surgical setting. For patients receiving therapeutic LMWH, therapy should be discontinued 12 to 24 hours prior to the procedure, or earlier in patients with renal dysfunction. Therapeutic doses of LMWH should not be restarted for 24 hours after a major procedure or with neuraxial anesthesia [14].

In the setting of overdose or hemorrhage, protamine completely reverses the antithrombin activity of LMWH, but only reverses 60% of the antifactor Xa activity (Table 93.9). If immediate reversal is warranted within 8 hours of LMWH administration, a protamine dose of 1 mg neutralizes 100 anti-Xa units or 1 mg of LMWH (Table 93.9). Initial dosing should max at 50 mg. Should bleeding continue, a second dose of 0.5 mg of protamine per 100 anti-Xa units or 1 mg of LMWH may be administered. Smaller protamine doses are required if the LMWH administration interval is beyond 8 hours [41]. Andexanet alfa is a modified recombinant form of factor Xa currently under investigation for reversal of LMWH [53,54]. This agent acts as a hemostatically inactive factor Xa decoy that binds free oral direct Xa inhibitors [54].

Heparin-induced thrombocytopenia (HIT) is an immune-mediated, hypercoagulable disorder that results from antibodies formed against the heparin-platelet factor 4 complex. The incidence in critically ill patients ranges from 0.3% to 0.5% and is associated with thrombocytopenia and life-threatening thrombosis in antibody-positive patients [55]. HIT typically occurs in patients who have been exposed to UFH or LMWH for 5 to 7 days, or even sooner in patients with prior exposure. A 30% to 50% decrease in platelet count occurring 5 to 14 days after the initiation of UFH or LMWH therapy or formation of a new thrombus during therapy may be indicative of HIT [55,56]. Platelet counts should be measured prior to the initiation of UFH or LMWH and monitored every other day for the first 4 to 10 days of therapy. Since heparin alternatives must be used in patients with HIT, direct thrombin inhibitors are the treatment of
choice [56].

Patients receiving heparin for a period of greater than 1 month are at risk for developing osteoporosis and vertebral fractures. Osteoporosis reportedly occurs less frequently in patients treated with LMWHs as compared to UFH [41].

**Fondaparinux**
Pharmacology, Pharmacodynamics, and Monitoring

Fondaparinux is a synthetic analog of the naturally occurring pentasaccharide found in heparins. Fondaparinux selectively and irreversibly binds to AT. This results in neutralization of factor Xa, which ultimately inhibits thrombin formation and thrombus development [41]. After subcutaneous administration, fondaparinux has a half-life of 17 to 21 hours in patients with normal renal function. Fondaparinux is excreted in the urine; clearance is reduced in patients with renal impairment. Laboratory monitoring of fondaparinux-specific anti-Xa assays is not recommended on a routine basis, although high-risk patients may warrant monitoring (Table 93.12) [41].

Clinical Indications

Fondaparinux is as safe and effective as heparins for treatment of DVT and PE and for thromboprophylaxis in surgical and medically ill patients [40]. Fondaparinux may be an option for thromboprophylaxis in the setting of HIT but conclusive data are not available [56].

Complications and Reversal of Effect

Fondaparinux is contraindicated in patients with severe renal impairment (calculated creatinine clearance $<30$ mL per minute) and should not be used for VTE prophylaxis in patients weighing less than 50 kg. No antidote exists for fondaparinux-related hemorrhage and reversal is further complicated by its prolonged half-life (Table 93.2) [15]. Recombinant factor VIIa (rVIIa) reverses the coagulation parameter alterations induced by fondaparinux, but the clinical utility is unknown [15]. With a short half-life (2 to 3 hours), rVIIa may require repeat dosing. The use of fondaparinux and neuraxial anesthesia or analgesia should follow the conditions used in clinical trials as closely as possible [27].

Direct Acting FXa-Inhibitors
Pharmacology, Pharmacodynamics, and Monitoring

Direct oral direct Xa inhibitors are the newest class of anticoagulants to clinical practice. They selectively bind to the active site of factor Xa and prevent the interaction with prothrombin [40]. Compared to indirect Xa inhibitors such as fondaparinux, these agents do not require antithrombin as a cofactor and inactivate both free and clot-bound factor Xa [40].

The oral direct Xa inhibitors differ in their pharmacokinetic parameters (Table 93.11). These agents have varying degrees of renal and hepatic elimination, elimination half-life, and susceptibility to drug interactions [40,57]. Oral direct Xa inhibitors were developed to provide more stable pharmacokinetic and dynamic profiles that eliminate the need for routine monitoring. Nevertheless, for patients undergoing invasive procedures or for critically ill patients with altered organ function, drug monitoring may be necessary [39]. Oral direct Xa inhibitors alter aPTT and INR values; however, these tests cannot be used to monitor therapy. Calibrated chromogenic anti-Xa assays provide a means to potentially monitor activity; however, exact therapeutic targets have yet to be described in practice [39].

Clinical Indications

Available agents include apixaban, edoxaban, and rivaroxaban, which are approved for the prophylaxis and treatment of thromboembolism in a variety of clinical settings (Table 93.12) [21,39,58]. Betrixaban is another oral agent under clinical investigation.

Complications and Reversal of Effect

Bleeding is the major complication of oral direct Xa inhibitors. These agents have demonstrated a lower rate of intracranial bleeding compared to warfarin; however, the rates of gastrointestinal bleeding were higher compared to warfarin [21,39]. Currently there are no available agents for the reversal of oral direct Xa inhibitors. Administration of activated and inactivated prothrombin complex concentrates (PCC) and recombinant factor VIIa may lower PT/INR values; however, impact on reversing bleeding and prothrombotic complications with these agents has not been evaluated (Table 93.2) [54]. Andexanet alfa is a modified recombinant form of factor Xa currently under investigation for reversal of oral direct acting Xa inhibitors [53,54]. This agent acts as a hemostatically inactive factor Xa decoy that binds free oral direct Xa inhibitors [54].
Direct Thrombin Inhibitors

Pharmacology, Pharmacodynamics, and Monitoring

Direct thrombin inhibitors (DTIs) include the older IV agents such as argatroban and bivalirudin, and the newest agent to the class, dabigatran, which is orally administered. They exert their antithrombotic effect by binding to the active site of thrombin and inhibiting thrombin-catalyzed reactions. This prevents fibrin formation, activation of coagulant factors V, VIII, XIII, protein C, and platelet aggregation [41].

Dabigatran etexilate is a small molecule oral prodrug with low bioavailability. After oral administration, it is converted to its active form dabigatran. The DTIs differ considerably in their pharmacokinetic parameters (Table 93.13) [59,60]. Bivalirudin has the shortest half-life, making it a particularly useful agent in the procedural or periprocedural period. DTI selection is predicated on patient-specific characteristics such as hemodynamic stability, hepatic function, and renal function. Critically ill patients typically require lower doses than those recommended by the manufacturer [41,59,60]. Intravenous DTIs are monitored using aPTT measured every 6 hours until the patient has sustainable therapeutic levels, and then the monitoring frequency can be extended [56]. Similar to the IV DTI’s, dabigatran prolongs the aPTT and the International Normalized Ration (INR); however, no recommendations are available on using this parameter to guide therapy. While ecarin clotting time (ECT) or thrombin time (TT) may be useful laboratory tests for monitoring coagulation during DTI therapy, these tests are often not widely available in the clinical setting [39].

Clinical Indications

Argatroban and bivalirudin are indicated for prophylaxis of thrombosis in patients with, or at risk for, HIT undergoing PCI. Bivalirudin is also indicated in the treatment of patients undergoing PCI as well as those with unstable angina/non-ST segment elevation MI undergoing PCI (Table 93.14) [60]. Dabigatran is indicated for the prevention of stroke and systemic embolism in patients with atrial fibrillation, for the treatment of VTE and to reduce the risk of recurrence [39].

# Complications and Reversal of Effect

Bleeding is one the most serious adverse effects of DTI therapy. A humanized monoclonal antibody fragment (Fab) that selectively binds to and inhibits the activity of dabigatran (idarucizumab) only is currently commercially available [53,61]. No specific reversal agents are available for other agents (Table 93.2). Recombinant factor VIIa has been reported
to be a potential option in the reversal of DTI bleeding [54]. Removal of dabigatran with hemodialysis or hemoperfusion has been reported to reverse its effects [54].

DTIs can produce elevation in the INR, an effect that is most pronounced with argatroban, and magnified when coadministered with warfarin. This laboratory interaction has misled clinicians to discontinue argatroban therapy prematurely, predisposing patients to venous limb gangrene [60]. With concurrent administration, the argatroban infusion should be stopped and the INR measured 4 to 6 hours. If the INR is within therapeutic range on warfarin alone, warfarin monotherapy can be continued, otherwise argatroban therapy should be resumed [60].

Oral Anticoagulants—Vitamin K Antagonists

Pharmacology, Pharmacodynamics, and Monitoring

Warfarin, a vitamin K antagonist (VKA), inhibits the enzyme vitamin K epoxide reductase complex (VKORC), which converts vitamin K to an active form. The absence of vitamin K reduces the hepatic production of functional coagulation thrombin, VII, IX, and X and the regulatory anticoagulant proteins C, S, and Z. Since thrombin has a longer half-life (60 to 72 hours) compared to the other factors (6 to 24 hours), at least 6 days of warfarin treatment is required for an antithrombotic effect [62].

Warfarin is extensively metabolized by the CYP450 isoenzyme system including CYP2C9, CYP1A1, CYP1A2, and CYP3A4. Several genetic polymorphisms have been identified with CYP2C9 and VKORC that may influence warfarin clearance and dose sensitivity [62].

In critically ill patients, alterations in coagulation factors, caused by reduced dietary vitamin K intake, hypoalbuminemia, antibiotic administration, acute hepatic injury, or hypermetabolic states, will impact the effects of warfarin. Furthermore, drug interactions alter warfarin absorption, clearance, and plasma protein binding. The interactions could have either synergistic or antagonistic effects [62].

Warfarin’s anticoagulant effect is measured using the INR [62]. The INR uses the international sensitivity index of the local thromboplastin reagent to standardize the laboratory result. The INR target range will vary based on indication and the patient’s risk for thromboembolic and bleeding complications (Table 93.15). Nomogram-based warfarin dosing is considered safer and more effective for reaching target INR goals. To
To prevent excessive anticoagulation, loading doses are avoided and low doses are employed for the elderly [44]. Frequent INR monitoring is necessary during initiation of therapy until steady state is reached.

Contraindications:
- Gangrene, preexisting
- Congestive heart failure
- Severe diabetes
- Excessive dietary vitamin K
- Elderly or debilitated patients (lower dosing may be required)
- Hepatic impairment
- Thyroid disorders
- Epidural catheters
- Infectious diseases or disturbances of intestinal flora, such as sprue or antibiotic therapy
- Poor nutritional state
- Protein C deficiency
- HITT
- Vitamin K deficiency

HITT, heparin-induced thrombocytopenia with thrombosis; MI, myocardial infarction; VTE, venous thromboembolism
Clinical Indications

Warfarin is effective for primary and secondary prevention of venous thromboembolism, for prevention of systemic embolism in patients with prosthetic heart valves or atrial fibrillation, and for prevention of stroke, recurrent infarction, or death in patients with acute MI [62,63].

Complications and Reversal of Effect

Treatment with warfarin increases the risk of major bleeding by 0.3% to 0.5% per year and the risk of intracerebral hemorrhage by approximately 0.2% per year compared to controls [54]. Important risk factors for hemorrhage include anticoagulant intensity, time within therapeutic range, and patient age. Higher goal INR (INR >3) has been directly associated with increased hemorrhage rates. Based upon the clinical scenario, an elevated INR can be managed by withholding therapy, decreasing dosing, or administration of reversal therapy (Table 93.2). For patients requiring reversal, available therapies include vitamin K, fresh frozen plasma (FFP), PCC, and rVIIa [54]. Vitamin K is given orally or parenterally. Oral vitamin K normalizes supratherapeutic INRs more rapidly than subcutaneous vitamin K, and the correction of INR is faster with IV route compared to oral administration and is both faster and more complete than subcutaneous administration [15,44,54,64]. For patients with an INR >4.5 but <10.0 and no significant bleeding, the next two doses of warfarin should be held, and low-dose (1 to 2.5 mg) oral vitamin K administered [44]. For patients with an INR >10, the vitamin K dose can be increased to 2.5 to 5 mg [62]. While 2.5 mg of vitamin K can reverse the effects of warfarin, in the setting of serious or life-threatening hemorrhage, warfarin should be held and vitamin K dosing up to 10 mg should administered by slow IV infusion [54].

The supplementation of coagulation factors with FFP or PCC’s may be more effective in cases of severe bleeding or where immediate reversal of the INR is necessary [54,65]. PCCs are available in several products globally with varying degrees of factor type and quantities. PCCs offer faster reversal than vitamin K and reduced intravenous fluid volume compared to FFP. PCCs with activated factors (i.e., FEIBA) may have an increased risk of thrombosis compared to nonactivated PCC’s [66]. Recombinant factor VIIa may be an option in patients with refractory bleeding; however, risk of prothrombotic events such as stroke and MI limits its use to life-threatening bleeds [54,67]. Nonhemorrhagic adverse events of warfarin include acute skin necrosis and limb gangrene. These
complications are typically observed on the third to eighth day of therapy [62].

In patients scheduled for surgery, warfarin may be continued, interrupted for approximately 5 days, or replaced with short-term parenteral or subcutaneous heparinoid bridge therapy depending on the patient’s risk for venous or arterial thromboembolism [14]. Warfarin can be re-initiated with or without bridge therapy after surgery. Recent findings suggest that the thromboembolism risk during warfarin treatment interruption may be overstated and bridging anticoagulation unnecessary in selected patient populations [68,69].

For warfarin-treated patients receiving neuraxial anesthesia with an indwelling catheter, the catheter should be removed when the INR is less than 1.5. Patients with a low risk of bleeding may undergo surgery with an INR of 1.3 to 1.5 [27,70].
FIBRINOLYTIC THERAPY

Pharmacology, Pharmacodynamics, and Monitoring

Fibrinolytic agents have been used clinically since the 1950s when streptokinase was shown to be effective in dissolving occlusive thrombi. Fibrinolytic agents promote the conversion of plasminogen to plasmin, which subsequently causes the degradation of fibrin clots [71]. Streptokinase and urokinase are naturally occurring first-generation fibrinolytic agents [72]. Recombinant tissue plasminogen activator (rt-PA) is a second-generation fibrinolytic that causes less overall systemic depletion of fibrinogen and plasminogen compared with streptokinase and urokinase. The half-life of rt-PA is less than 5 minutes when administered as a bolus followed by rapid continuous infusion (Table 93.16). Third-generation fibrinolytic agents are synthetic agents with increased fibrin specificity compared to first-generation fibrinolytics and extended half-lives compared to rt-PA [72].

Clinical Indications

Fibrinolytic therapy is administered to patients with acute ischemic
stroke, VTE, acute MI, peripheral arterial occlusion, and in those patients requiring venous catheter maintenance (Table 93.17). A clear role for fibrinolytic therapy, compared with surgical revascularization, for acute limb ischemia has yet to be defined. There is wide variation in fibrinolytic agents employed, doses studied, patient populations, and endpoints of therapy. The greatest benefit has been shown for patients presenting with acute ischemia <14 days who are at low risk for irreversible ischemia [73]. A common use for fibrinolytic agents is to clear thrombotic occlusions within central venous and dialysis catheters. This therapy is both effective and safe since little to no active drug reaches the systemic circulation [74].

Complications and Reversal of Effect

Bleeding is the most common and severe complication of fibrinolytic therapy. The most common areas of bleeding are the gastrointestinal and genitourinary tracts as well as sites of interrupted vascular integrity, including catheter access sites, gingiva, and skin \[75–77\]. Various risk factors for hemorrhage have been identified, but application to clinical practice is limited \[78\].

Patients receiving fibrinolytic therapy should be closely monitored for intracerebral hemorrhage. Intracerebral hemorrhage should be suspected in patients with sudden focal neurological deterioration (over minutes to hours), decreased level of consciousness, new-onset headache, nausea, vomiting, or acute increases in blood pressure during and within 24 hours of fibrinolytic treatment. Prompt treatment should ensue with replacement of coagulation factors, platelets, FFP, red blood cells, and aminocaproic acid. Due to its derivation from Streptococcus, patients may have performed antibodies to streptokinase from prior streptococcal infections. Adverse drug events include allergic reactions, anaphylaxis, fever, and hypotension.
REFERENCES

INTRODUCTION

Although the incidence of aggressive hematologic malignancies like acute myeloid leukemia (AML), acute lymphoblastic leukemia (ALL), and intermediate- and high-grade non-Hodgkin lymphomas is low, these potentially curable diseases frequently require intensive care unit (ICU) management at presentation to prevent early mortality and achieve disease remission. Patients with hematologic malignancies account for approximately 2% of all ICU admissions [1,2]. Approximately 7% of patients with hematologic malignancies admitted to the hospital will become critically ill [3]. The most frequently reported indications for ICU admission in patients with hematologic malignancies are respiratory failure (26% to 91%), severe sepsis (8% to 64%), neurologic impairment (14% to 23%), and acute renal failure (14% to 23%). For all critically ill patients with hematologic malignancies, ICU mortality, in-hospital mortality and 6-month mortality rates are 23% to 62%, 54% to 82%, and 66% to 83%, respectively [1–12]. Risk factors for death in the ICU include high disease severity score (APACHE II, SAPS II, SOFA), poor performance status, vasopressor use, leukopenia, increasing number of organ failures, and acute renal failure (see Table 94.1). In a large prospective study of 1,100 critically ill patients with hematologic malignancies, earlier admission to the ICU and cancer in remission were associated with improved hospital survival [12]. Notably, mechanical ventilation has not been consistently associated with increased risk of death in this patient population, and some studies suggest improved outcomes with early endotracheal intubation [2,13]. In addition, survival in patients with hematologic malignancies admitted to the ICU after chemotherapy alone versus hematopoietic cell transplant (HCT) are not
different, suggesting that critically ill HCT patients should be treated aggressively on ICU admission [14,15]. In fact, when matched for severity of acute illness upon ICU admission, survival of patients with hematologic malignancies and nononcologic patients appears to be similar [1].

OVERVIEW OF HEMATOLOGIC MALIGNANCIES

Acute Myeloid Leukemia

AML accounts for 22% to 54% of hematologic malignancy admissions to the ICU [1,2,4,6–11]. Patients with AML may require ICU admission for disease- or treatment-related complications including sepsis (frequently complicated by neutropenia), bleeding caused by thrombocytopenia and occasionally acute disseminated intravascular coagulation (DIC) and multiple organ failure.

The incidence of AML in the United States is 3.5 cases per 100,000 persons per year with approximately 12,000 new cases diagnosed annually. More than half of newly diagnosed AML patients are over 65 years of age and a third are older than 75 years. Five-year survival rates are approximately 50% in adults under the age of 45 years but drop to less than 10% in patients over the age of 65 [16].

AML arises from the acquisition of genetic mutations in myeloid precursors or stem cells leading to various degrees of maturation arrest, unregulated proliferation, and resistance to apoptosis. By the World Health Organization 2008 classification system, the diagnosis of AML requires myeloid blasts to comprise 20% or more of nucleated cells in the peripheral blood or bone marrow except in cases of AML with the recurrent cytogenetic abnormalities t(15;17), t(8;21), inv(16)/t(16;16), myeloid sarcoma (a tumor of myeloblasts), and some cases of erythroleukemia. The recurrent cytogenetic abnormalities t(15;17), t(8;21), inv(16)/t(16;16) and normal cytogenetics accompanied by gene mutations in NPM1 or both alleles of CEBP-α confer a better prognosis in terms of risk of relapse, and the majority of patients obtain durable complete remissions with chemotherapy alone [17]. Conversely, patients with poor risk cytogenetics and those with normal cytogenetics accompanied by mutations in the FLT3 protooncogene have a low likelihood of durable remission with chemotherapy alone and typically undergo allogeneic HCT in first complete remission [17].

Standard induction chemotherapy for AML using 3 days of intravenous (IV) anthracycline (daunorubicin, idarubicin) or anthracyclenedione (mitoxantrone) and 7 days of cytarabine by continuous IV infusion,
ideally initiated within 5 days of diagnosis for de novo AML, leads to complete remission rates of 60% to 80% in young adults under 60 years of age and 50% in patients over 60 years of age. Postremission therapy is tailored to pretreatment risk status, performance status, comorbidities, and age, and may consist of chemotherapy alone or myeloablative or reduced-intensity conditioning allogeneic HCT [18].

Acute Promyelocytic Leukemia

Acute promyelocytic leukemia (APL) accounts for 5% to 6% of all AML with approximately 600 to 800 new diagnoses made each year in the United States. APL frequently presents with acute DIC that can be rapidly fatal due to intracerebral, pulmonary, or gastrointestinal (GI) hemorrhage, in all accounting for 50% to 60% of early deaths. Early suspicion and treatment of APL, even prior to definitive genetic diagnosis, is important to reduce the risk of life-threatening hemorrhage [19]. Paradoxically, patients are also at risk of thrombotic events that complicate about 10% to 12% of cases, frequently in those with expression of CD2, CD15, and FLT3-ITD mutation APL occurs due to arrest of myeloid differentiation at the promyelocyte stage leading to accumulation of leukemic promyelocytes in the bone marrow, blood, and tissues. Morphologically, leukemic promyelocytes typically have variable nuclear morphology with bilobed or reniform nuclei, prominent cytoplasmic granules, and numerous large Auer rods, frequently in bundles. Approximately 5% of APL presents as a microgranular variant characterized by few or absent granules. Patients with this microgranular variant tend to have higher presenting white blood cell counts, placing them at higher risk of complications and relapse. Except in rare instances, APL is characterized by the presence of the recurrent cytogenetic abnormality t(15;17)(q22;q12) leading to a PML-RAR-α fusion gene that can be demonstrated by cytogenetic analysis, fluorescence in situ hybridization (FISH) and quantitative reverse transcription polymerase chain reaction (RT-PCR). The chimeric PML-RAR-α protein is the target of therapy with all-trans-retinoic acid (ATRA) and arsenic trioxide (ATO), agents that cause degradation of the PML-RAR-α oncoprotein thereby promoting terminal differentiation of leukemic promyelocytes [20,21].

The diagnosis of APL should be considered in any patient with a new diagnosis of leukemia, especially if accompanied by clinical and laboratory evidence of acute DIC. Early institution of treatment with the
differentiating agent ATRA is indicated upon suspicion of APL to reduce the risk of fatal bleeding [19]. Careful review of the peripheral blood smear from new leukemia patients in consultation with hematologists and hematopathologists should be performed to look for characteristic hypergranular leukemic promyelocytes. Expedited performance of flow cytometry, specifically evaluating for coexpression of CD34, CD15, and CD13 on the surface of leukemic cells can aid in diagnosing the microgranular variant of APL.

Greater than 70% of APL patients attain prolonged remissions with current treatment strategies. Induction chemotherapy regimens generally combine ATRA with ATO or ATRA with an anthracycline, typically idarubicin or daunorubicin [19,22]. ATO is highly active against APL and in combination with ATRA produces complete response rates over 90% [22]. ATRA or ATO, however, may cause a fatal differentiation syndrome (DS) characterized by fever, dyspnea, pulmonary infiltrates, pleuropericardial effusions, weight gain, peripheral edema, renal failure, and hypotension.

**Acute Lymphoblastic Leukemia**

ALL results from the acquisition of genetic mutations in lymphoid progenitor or stem cells resulting in the arrest of cells at an early stage of differentiation. In 2009, about 5,760 people were diagnosed with ALL in the United States with a median age of 13 years. ALL patients comprise 9% to 27% of ICU admissions for hematologic malignancies [1,2,4,6–11]. The 10-year survival among all adults with ALL is less than 30%.

Favorable disease characteristics in ALL include ages 1 to 15 years, presenting WBC <30,000 per μL for B-cell ALL or <50-100,000 per μL for T-cell ALL, rapid achievement of complete remission, and minimal residual disease negativity whereas age >35 years is unfavorable. Cases with t(9;22)/BCR-ABL (Philadelphia chromosome, Ph), representing 15% to 20% of adult cases of ALL, or t(4;11)/MLL-AF4 translocations typically fare poorly, with historical survival rates of less than 10% with chemotherapy alone and long-term survival after allogeneic HCT ranging 20% to 45%. The addition of tyrosine kinase inhibitors targeting BCR-ABL1 (e.g., imatinib, dasatinib, nilotinib) to chemotherapy for Ph+ ALL has dramatically improved survival in patients not undergoing allogeneic HCT.

Clinical trial regimens in the last decade have improved complete remission rates to 74% to 93% with 5-year survival rates as high as 48%. Therapy for ALL typically spans 2 to 3 years and includes induction therapy, postremission therapy, central nervous system (CNS) prophylaxis and maintenance chemotherapy in patients who do not undergo HCT. Induction therapy for ALL typically combines vincristine,
an anthracycline (e.g., daunorubicin), and a corticosteroid (prednisone or dexamethasone) typically with L-asparaginase and/or cyclophosphamide. Prophylaxis against CNS relapse includes intrathecal chemotherapy with methotrexate with or without cytarabine and frequently high-dose IV methotrexate. Postremission therapy typically includes the same agents used in induction as well as methotrexate, cytarabine, and 6-mercaptopurine, among other agents. Maintenance therapy consists of oral methotrexate and 6-mercaptopurine often with pulses of vincristine and corticosteroids. Imatinib, dasatinib, and nilotinib inhibit the chimeric BCR-ABL1 tyrosine kinase produced by the Ph chromosome and improve complete remission and survival rates in Ph+ ALL. Allogeneic HCT is often performed in adult patients with ALL, although recent data suggests that patients who are negative for minimal residual disease at the completion of induction chemotherapy may not require allogeneic HCT to maximize likelihood of survival [23].

Aggressive Non-Hodgkin Lymphomas

Diffuse large B-cell lymphoma (DLBCL) is an aggressive non-Hodgkin lymphoma of intermediate histologic grade that typically presents with rapidly enlarging lymph nodes or extranodal masses frequently with symptoms of organ compromise from lymphomatous involvement of extranodal sites. Diagnosis is typically made by excisional biopsy of a lymph node or mass showing large lymphoid cells that completely efface lymph node architecture. Malignant B cells express CD19, CD20, and CD22 with variable expression of surface immunoglobulin, CD5, and CD10. Common genetic abnormalities in DLBCL include constitutive expression of the transcriptional repressor Bcl-6, the antiapoptotic protein Bcl-2, and/or the transcription factor c-myc. The International Prognostic Index for aggressive lymphomas uses five unfavorable variables to establish risk status: age greater than 60 years, poor performance status, advanced stage (Ann Arbor Stage III or IV disease), extranodal involvement at more than one site, and elevated serum lactate dehydrogenase. First-line combination chemotherapy with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) in combination with the humanized monoclonal anti-CD20 antibody rituximab results in 2-year overall survival rates of 70% to 90%.

Burkitt lymphoma (BL), which has the fastest growth rate of any human malignancy, is an aggressive non-Hodgkin lymphoma with endemic, sporadic, and immunodeficiency-associated clinical variants. BL typically presents with rapidly progressive nodal and extranodal disease, commonly in the abdomen and GI tract leading to nausea, vomiting, anorexia, bowel obstruction, and GI bleeding. Advanced stage is common at diagnosis with bone marrow involvement in 30% to 38%
and CNS involvement in 13% to 17% of adults. Morphologically, lymphoma cells are medium-sized with deeply basophilic cytoplasm containing cytoplasmic lipid vacuoles and a high proliferative index of greater than 90%. A leukemic variant exists and can be distinguished from ALL by surface expression of immunoglobulin, CD20, and CD10, without coexpression of TdT or CD34. BL is genetically characterized by chromosomal translocations that lead to constitutive expression of c-myc, typically t(8;14) and rarely t(2;8) or t(8;22). High-intensity, brief-duration chemotherapy, typically with cyclophosphamide, doxorubicin, vincristine, and antimetabolite-containing regimens, with intensive CNS prophylaxis, have led to 1-year remission rates as high as 86%. The bulky disease and high cell proliferation rates seen in both DLBCL and BL place patients at high risk of tumor lysis syndrome, and prophylactic treatment with allopurinol to prevent hyperuricemia is typically given prior to chemotherapy.

Other Malignancies

Other notable hematologic malignancies frequently requiring ICU level care are multiple myeloma, Waldenstrom macroglobulinemia and myeloproliferative neoplasms such as chronic myeloid leukemia, essential thrombocytopenia, polycythemia vera, and chronic idiopathic myelofibrosis. In multiple myeloma, spinal cord compression may occur due to encroachment of the spinal canal by epidural plasmacytomas and/or from pathologic fracture of spinal vertebrae. Emergent imaging of the entire spine with magnetic resonance imaging is required for diagnosis (see Chapter 95). In Waldenstrom macroglobulinemia, high concentrations of monoclonal immunoglobulin M (IgM) paraprotein in the serum can lead to the hyperviscosity syndrome manifest as mucosal bleeding, confusion, seizures, coma, visual disturbance, and/or headache as well as cryoglobulinemia, cold agglutinin hemolytic anemia, and plasma volume expansion leading to congestive heart failure. Myeloproliferative neoplasms may lead to life-threatening hemorrhage or thrombosis, requiring critical care (see Chapter 95).
DISEASE AND TREATMENT-RELATED COMPLICATIONS

Hyperleukocytosis and Leukostasis

In AML, hyperleukocytosis, generally defined as a circulating blast count greater than 100,000 per μL, occurs in 5% to 18% of patients at initial presentation. Early mortality during initial treatment of patients with hyperleukocytic AML ranges from 5% to 30% with advanced age, poor performance status, coagulopathy, respiratory compromise, and organ failure associated with early death [24]. Hyperleukocytosis in AML is frequently associated with leukostasis manifesting as respiratory failure, visual disturbances, intracranial hemorrhage, and renal failure.

Leukostasis, although typically associated with hyperleukocytosis, can occur at white blood cell counts less than 50,000 per μL (likely caused by interpatient variability in leukemia cell biology and individual susceptibility). Myeloid leukemic blasts are less deformable than mature white blood cells possibly predisposing to formation of aggregates of cells in the small blood vessels, tissue ischemia, endothelial damage, and tissue infiltration. In addition, expression of specific cell surface adhesion molecules on leukemia cells and endothelial cell activation by cytokines secreted by leukemic blasts may play important roles in promoting leukostasis. For instance, the expression of CD56/NCAM on the surface of leukemia cells in myelomonocytic AML correlates with the development of leukostasis [25]. In vitro, myeloid blasts promote their own adhesion to the vascular endothelium by upregulating expression of ICAM-1, VCAM-1, and E-selectin on endothelial cells [26]. Expression of the cell surface integrin CD11c on the surface of AML blasts is associated with increased early death risk in the setting of hyperleukocytosis [27]. In ALL, hyperleukocytosis is rarely associated with symptomatic leukostasis except with extreme hyperleukocytosis (WBC >400,000 per μL) possibly due to the smaller size, easier deformability, and decreased vascular endothelium adherence of lymphoblasts. In AML with hyperleukocytosis, most studies have not shown a demonstrable difference in complete response rates, disease-free survival or overall survival after treatment. However, the presence of pulmonary leukostasis, hepatomegaly, hyperbilirubinemia, and hypofibrinogenemia are predictors of poor outcome in patients with hyperleukocytosis [24].

Hydroxyurea at doses of 20 to 30 mg/kg/d or more can reduce peripheral leukocyte counts, and generally requires 1 to 2 days to take effect. Red blood cell transfusions should be avoided until the leukocyte
count is less than 50,000 per μL to avoid ischemic events such as stroke or acute coronary syndrome. Although invasive, leukapheresis is a relatively safe procedure and is frequently used in combination with hydroxyurea to rapidly lower circulating blast counts and theoretically decrease the risk of tumor lysis syndrome and progressive leukostasis (see Chapters 89 and 96). Two blood volumes (140 mL per kg) are processed in the typical leukapheresis procedure. Studies have failed to show a consistent clinical benefit with the use of leukapheresis in hyperleukocytic leukemia [28,29], although some uncontrolled retrospective single institution studies show reduction in early mortality in patients undergoing leukapheresis without an overall survival benefit [28]. A recent meta-analysis of 21 studies of hyperleukocytic AML failed to show an early mortality benefit with leukapheresis or early institution of chemotherapy including hydroxyurea [29]. In APL patients presenting with hyperleukocytosis and organ failure, leukapheresis is contraindicated due to the risk of exacerbating acute DIC, initiating vasomotor instability, and increasing induction death [19].

**Hyperviscosity Syndrome**

The hyperviscosity syndrome occurs in 30% of patients with Waldenstrom macroglobulinemia (also called lymphoplasmacytic lymphoma with IgM monoclonal gammopathy) at presentation and is defined by the presence of increased serum viscosity with neurologic symptoms related to impaired blood flow including headache, vertigo, dizziness, visual impairment, hearing impairment, tinnitus, nystagmus, stupor, stroke, dementia, and coma [30]. In addition, mucosal bleeding, including GI hemorrhage, renal failure, and congestive heart failure because of plasma volume expansion and concomitant anemia may occur. Elevated serum IgM, with its large pentameric structure, is most commonly associated with hyperviscosity, although the syndrome has been reported with immunoglobulin A, immunoglobulin G, and κ light chain multiple myeloma. Normal serum viscosity measures 1.4 to 1.8 centipoises and symptomatic hyperviscosity typically occurs at greater than 4 centipoises.

Emergent plasmapheresis is indicated for symptomatic hyperviscosity. One to two plasma volumes are typically exchanged and replaced with 5% albumin in patients with low bleeding risk or fresh frozen plasma (FFP) in patients at high risk of bleeding. Symptoms typically resolve quickly but neurologic deficits can remain. Red blood cell transfusions should be avoided if possible until serum viscosity is lowered (see Chapter 89). Definitive treatment for the underlying malignancy should be instituted quickly to control paraprotein production. Procedural risks include depletion of clotting factors when 5% albumin is used as the exchange
fluid, hypocalcemia from citrate anticoagulant use, dialysis catheter-related infection, pneumothorax or thrombosis, and complications from FFP administration including anaphylaxis, blood-borne infections, and transfusion-related acute lung injury.

**Bleeding**

Bleeding in hematologic malignancies is a common cause of morbidity and mortality. DIC and thrombocytopenia are common etiologies, but acquired clotting factor deficiencies can also predispose to life-threatening hemorrhage.

**Disseminated Intravascular Coagulation**

Acute DIC is a common cause of morbidity and mortality during the treatment of many hematologic malignancies and is especially characteristic of APL and to a lesser degree other forms of acute leukemia. Sepsis, especially gram-negative sepsis occurring in the setting of disease or treatment-related neutropenia, is a common cause of DIC as well. Complicating the diagnosis of DIC is the frequent presence of hepatic failure due to malignant infiltration of the liver or treatment-related hepatotoxicity. Clinically, patients are at high risk of death from bleeding and can develop oozing from IV lines and surgical sites, purpura, pulmonary hemorrhage, intracranial hemorrhage, GI bleeding, and multiple organ failure.

Acute DIC results from pathologic coagulation within small blood vessels, typically from the release of tissue factor or endotoxin exposure, leading to unmitigated activation of coagulation and consumption of coagulation factors and platelets. Depletion of clotting factors and platelets, activation of plasmin, and the production of anticoagulant fibrin split products can lead to severe bleeding. Laboratory hallmarks of acute DIC include thrombocytopenia, prolongation of clotting times, hypofibrinogenemia, elevated fibrin split products, and sometimes schistocytes on the peripheral blood smear.

The coagulopathy observed in APL resembles acute DIC but with some subtle differences. In APL, leukemic cells produce tissue factor and high levels of a cysteine protease called cancer procoagulant, both of which are downregulated by ATRA treatment in primary and cultured leukemic APL blasts [31–34]. Tissue factor in conjunction with activated Factor VII activates Factor X, whereas cancer procoagulant can directly activate Factor X leading to pathologic coagulation. In addition, rapid death of malignant cells leads to increased thrombin generation [35]. Unlike acute DIC, antithrombin and protein C levels are maintained in the coagulopathy of APL [36]. Increased fibrinolysis also complicates APL
Reversal of acute DIC requires effective treatment of the underlying cause. Supportive care includes early management of sepsis including the administration of broad-spectrum antibiotic coverage with antipseudomonal activity in neutropenic patients and reversal of organ dysfunction when possible. In the setting of APL, early institution of ATRA combined with cytotoxic chemotherapy in high-risk patients with WBC >10,000 per μL is indicated to reduce the burden of leukemic promyelocytes. DIC typically resolves within 48 hours of initiation of ATRA in this setting.

With acute DIC, frequent monitoring of complete blood count, prothrombin time (PT), partial thromboplastin time (PTT), and fibrinogen three to four times a day is prudent to monitor the consumptive process and guide replacement of platelets and coagulation factors. In patients with APL-associated DIC who are bleeding or who are at high risk of bleeding, maintenance of platelet count above 30,000 to 50,000 per μL and fibrinogen above 100 to 150 mg per dL with platelet and cryoprecipitate transfusions has been recommended [19]. FFP also may be given to reduce the prolonged PT and PTT. By inhibiting thrombin and Factor Xa, low-dose heparin (4 to 5 U/kg/h) could theoretically improve severe bleeding in acute DIC by limiting fibrinogen and platelet consumption, plasminogen activation, and fibrin split product production. Results of clinical studies, however, have been equivocal, and routine use of heparin to prevent or treat acute DIC-related bleeding is not universally standard. Conversely, thrombosis may occur in acute DIC, and in this setting, the administration of low-dose heparin may be beneficial. The role of activated protein C, soluble thrombomodulin, tranexamic acid, and aminocaproic acid in the management of DIC in hematologic malignancy patients is unclear. A meta-analysis of four randomized controlled trials in patients with acute
or chronic leukemias was unable to show any benefit to the use of activated protein C, soluble thrombomodulin, and tranexamic acid in treating leukemia patients with DIC [41]. Rare patients with intractable bleeding despite standard measures may benefit from tranexamic acid or aminocaproic acid but with a risk of microvascular thrombosis and organ failure.

Thrombocytopenia

Thrombocytopenia in patients with hematologic malignancies can be caused by bone marrow infiltration by malignant cells, myelosuppression from chemotherapy and other medications, bacterial sepsis, acute DIC, immune thrombocytopenia, and/or hypersplenism from splenomegaly. The risk of major hemorrhage dramatically increases at platelet counts less than 5,000 per μL and the use of prophylactic platelet transfusions, starting in the 1970s, typically with a transfusion threshold of 20,000 per μL, reduced the frequency of fatal bleeding in this population to less than 1%. However, this strategy led to an increased demand for platelet concentrates.

The issue of the optimal platelet count to trigger a prophylactic platelet transfusion has been addressed. A 2004 Cochrane Database systematic review included three prospective randomized studies comparing prophylactic platelet transfusions at platelet counts of 10,000 per μL versus 20,000 per μL. None of these studies showed significant differences in severe bleeding events or mortality but the studies were small and possibly underpowered to show noninferiority of the lower transfusion threshold [42]. The risk of spontaneous hemorrhage in patients without concomitant coagulopathy or acute DIC, platelet dysfunction, fever, mucositis, or uncontrolled hypertension appears acceptable until platelets are below 10,000 per μL. Safely minimizing the platelet dose per prophylactic transfusion has been studied as well. A 2010 study randomized 1,272 patients undergoing chemotherapy or HCT for hematologic and nonhematologic malignancies to receive 1.1 × 10^{11}, 2.2 × 10^{11}, or 4.4 × 10^{11} platelets per m² of body surface area to be given prophylactically for platelet counts less than 10,000 per μL. The lowest dose group required fewer platelets overall but required more transfusions (five vs. three per patient per treatment course). Bleeding rates of all grades were similar between the groups with no deaths from hemorrhage in the low- and medium-dose groups supporting the use of low-dose platelet transfusions [43]. Avoiding drugs that cause platelet dysfunction (especially aspirin, nonsteroidal antiinflammatory drugs [NSAIDs], Cox-2 inhibitors, and clopidogrel), treating underlying coagulopathy, and reversing renal dysfunction are important adjuncts to preventing bleeding in thrombocytopenic patients as well.
Acquired von Willebrand Syndrome

The acquired von Willebrand syndrome (aVWS) results from a reduction in the level of von Willebrand factor (VWF) and may rarely occur in monoclonal gammopathy of undetermined significance, Waldenstrom macroglobulinemia, multiple myeloma, non-Hodgkin lymphomas, and myeloproliferative neoplasms, especially essential thrombocythemia. Treatment of the underlying malignancy to decrease tumor burden or reduce elevated platelet counts is generally effective in resolving acquired von Willebrand disease. Management may include platelet apheresis in the setting of extreme thrombocytosis and active bleeding. High-dose intravenous immunoglobulin (dose, 1 g/kg/d for 2 days) may be considered in patients with lymphoid neoplasms who have inhibitory antibodies to VWF. For treatment of acute bleeding, desmopressin (dose, 0.03 μg per kg IV) or purified plasma-derived vWF/FVIII concentrates may be considered. Aspirin and NSAIDs should be avoided until aVWS has resolved.

Pulmonary Complications

Mechanical ventilation is associated with poor outcomes in patients with hematologic malignancies. Mortality ranges from 39% to 82%, although most studies of respiratory failure in patients with hematologic malignancies are retrospective and have failed to match mechanically ventilated and nonventilated patients for degree of respiratory compromise. Hampshire et al. retrospectively studied 7,689 cases of hematologic malignancies requiring ICU admission in England, Wales, and Northern Ireland. When matched for PaO₂:FiO₂ ratios, mechanically ventilated hematologic malignancy patients had reduced mortality compared with nonventilated hematologic malignancy patients (mortality 67% vs. 85% for PaO₂:FiO₂ <100 mm Hg, 50% vs. 69% for PaO₂:FiO₂ 100 to 199 mm Hg) [2]. In a smaller study, invasive mechanical ventilation within 24 hours after ICU admission was associated with lower mortality rates compared with patients receiving noninvasive positive pressure ventilation [13]. After HCT, however, patients who require mechanical ventilation appear to fare less well. Short-term mortality is 82% to 96% and worsens to 98% to 100% in the setting of combined renal and hepatic failure. Only 9% to 14% of mechanically ventilated HCT patients are alive 6 months after ICU admission.
Diagnostic approaches to identify the etiology of respiratory failure include blood, urine, and sputum cultures, blood and urine infectious serologies, diagnostic imaging, bronchoscopy, and surgical lung biopsy. Flexible bronchoscopy with bronchoalveolar lavage (BAL) detects pulmonary infections in approximately 50% of patients with hematologic malignancies presenting with respiratory deterioration leading to a change in antimicrobial therapy in 38% of patients [44,45]. In one study, there was no survival advantage to BAL, and respiratory deterioration requiring mechanical ventilation occurred in 36% of patients as a short-term consequence of BAL highlighting the need for careful patient selection and the broad use of noninvasive diagnostic tests prior to pursuing BAL [45]. In two retrospective studies of surgical lung biopsy among hematologic malignancy patients with unexplained pulmonary infiltrates, a specific diagnosis was made in 62% to 67% of patients and led to change in therapy 40% to 57% of the time. A specific diagnosis was significantly associated with decreased mortality in both studies (absolute reduction in mortality, 29% to 33%) [46,47].

Infection is the most common identifiable cause of respiratory distress in hematologic malignancies. Pulmonary hemorrhage, diffuse alveolar damage, pulmonary embolism, and congestive heart failure are the most common identifiable noninfectious causes. Pulmonary infections are typically caused by Pseudomonas aeruginosa, Staphylococcus aureus, and streptococcal species with Legionella pneumophila and mycobacterial infections being less common pathogens. Prolonged neutropenia from underlying disease or myelotoxic chemotherapy places patients at risk of mycelial fungal pneumonia with Aspergillus spp. being the most common offenders. Patients with lymphoid malignancies and those treated with allogeneic HCT are also at risk of Pneumocystis jiroveci pneumonia and viral pneumonias including cytomegalovirus (CMV) infection. Effective antimicrobial treatment can be difficult in this group of patients as mixed infections and antimicrobial resistance are common. Ganciclovir and related antiviral agents in combination with IV immunoglobulin have reduced the mortality of CMV pneumonia in HCT patients [48].

Noninfectious etiologies of respiratory failure in patients with hematologic malignancies, including those undergoing HCT, include cardiogenic pulmonary edema, diffuse alveolar hemorrhage (DAH), engraftment syndrome, idiopathic pneumonia syndrome (IPS), bronchiolitis obliterans syndrome (BOS), cryptogenic organizing pneumonia (COP), granulomatous inflammation and malignant infiltration of the lungs. Chemotherapeutic agents such as carmustine (BCNU), busulfan, and bleomycin are known to cause lung injury. ICU patients with hematologic malignancies are also at high risk of pulmonary embolism given immobility, active malignancy, and
frequently DIC.

DAH accounts for 20% to 30% of pulmonary complications after allogeneic HCT and is a cause of early death in 1.5% of patients with APL. DAH occurs with hematopoietic engraftment in allogeneic HCT patients and presents with cough, hemoptysis, declining hemoglobin, and hypoxemia with diffuse alveolar filling on lung imaging. Serial lavage during BAL classically shows increasingly bloody fluid return. Treatment for DAH includes replacement of platelets and coagulation factors to maintain hemostasis, supportive mechanical ventilation as needed, and corticosteroids. Small retrospective studies support the use of high-dose corticosteroids (methylprednisolone 30 to 1,500 mg per day) for treatment of DAH after allogeneic HCT. However, a recent retrospective single-center study of 119 patients found that the use of medium to high doses of corticosteroids was associated with higher ICU mortality [49]. Administration of parenteral recombinant activated Factor VII has been associated with resolution of DAH occurring after HCT in case reports and series [50,51].

In addition to DAH, early-onset noninfectious pulmonary complications after allogeneic HCT include pulmonary engraftment syndrome and IPS. Pulmonary engraftment syndrome mimics DAH and is characterized by fever, pulmonary infiltrates, hypoxia, and a skin rash developing early after HCT, coinciding with recovery of circulating neutrophils (ANC >500 per μL). It is typically a self-limited process lasting 1 to 2 weeks that is treated with supportive care and a short course of standard-dose corticosteroids (approximately 1 mg per kg prednisone or equivalent) [52]. IPS, which occurs in about 10% of HCT patients, presents with fever, cough, shortness of breath, hypoxemia, and diffuse bilateral pulmonary infiltrates without an identifiable infection by BAL. IPS occurs after hematopoietic engraftment with a median onset of 21 to 52 days after HCT and carries a 60% to 90% mortality. Pathologically, the syndrome is characterized by an interstitial infiltrate comprised primarily of lymphocytes. In a study of 15 patients with IPS, the combination of etanercept, a tissue necrosis factor-α antagonist, and corticosteroids given at 2 mg per kg daily (methylprednisolone equivalent) resulted in 10 complete responses and a 28-day survival of 73% [53].

Late-onset noninfectious pulmonary complications after HCT typically occur more than 3 months after stem cell infusion and include BOS and COP (formerly referred to as bronchiolitis obliterans with organizing pneumonia). BOS occurs in 14% of allogeneic HCT patients with chronic graft-versus-host disease (cGVHD). BOS is a manifestation of cGVHD whereby alloreactive donor T cells generate fibromuscular proliferation of the walls of small airways. This produces an obstructive physiology with air trapping and occasionally the need for supplemental oxygen. There is no standard treatment for BOS beyond immunosuppression for cGVHD,
although aerosolized corticosteroids, oral azithromycin, have been used and montelukast (a leukotriene receptor antagonist). COP tends to occur late after allogeneic HCT and demonstrates restrictive pulmonary physiology. COP is associated with GVHD and may be a manifestation of the disease itself. Some insult triggers inflammation of the small airways causing a proliferative bronchiolitis and deposition of cellular matrix materials into alveoli leading to hypoxemia. Unlike BOS, COP is reversible and corticosteroid responsive.

Common pulmonary processes complicating hematologic malignancies are summarized in Table 94.2.

**Infection**

Chemotherapy for high-grade hematologic malignancies commonly causes neutropenia and cellular and/or humoral immunosuppression. Unless receiving immunosuppressive chemotherapy agents (e.g., fludarabine, cladribine), AML patients typically retain adequate cellular and humoral immunity even during periods of severe bone marrow suppression. Neutropenic patients are susceptible to infections by endogenous skin, genitourinary and GI tract flora as well as hospital-acquired infections including nosocomial and ventilator-associated pneumonias, central venous line infections, *Clostridium difficile* colitis, and infections with *Pseudomonas* spp., *Stenotrophomonas* spp., *Burkholderia* spp., vancomycin-resistant enterococcus, methicillin-resistant *S. aureus* (MRSA), and extended-spectrum β-lactamase-producing gram-negative organisms. Prolonged neutropenia, especially with concomitant corticosteroid administration or diabetes mellitus, places patients at risk of invasive fungal infections, especially *Aspergillus* spp. Immunosuppressed patients, particularly those with lymphoid malignancies and those undergoing allogeneic HCT, are at additional risk of opportunistic infections such as *P. jirovecii*, herpes simplex virus, varicella zoster virus, and CMV. Treatment of febrile patients with neutropenia or immunosuppression involves rapid evaluation for infectious causes and initiation of empiric broad-spectrum antibiotic therapy with adequate coverage of *P. aeruginosa* and MRSA. For patients with persistent fever and prolonged neutropenia (>7 days), the addition of antifungal therapy targeting *Aspergillus* spp. is indicated. Afebrile neutropenic patients with an absolute neutrophil count less than 500 per μL should receive daily prophylactic treatment with a fluoroquinolone antibiotic. A meta-analysis of 95 trials including 52 trials using fluoroquinolone prophylaxis showed that neutropenic patients receiving...
fluoroquinolone prophylaxis had significant decreases in all-cause mortality, infection-related mortality, fever and documented infection with a nonsignificant trend toward increasing antimicrobial resistance [54]. The use of granulocyte-stimulating growth factors (e.g., G-CSF) in patients receiving myelotoxic chemotherapy reduces total days of neutropenia and hospital length of stay without promoting tumor cell growth or affecting overall survival.

Differentiation Syndrome

DS, formerly referred to as retinoic acid syndrome, is a potentially fatal process of unclear mechanism (likely, detrimental cytokine storm) that occurs in 2% to 27% of APL patients treated with ATRA or ATO [55]. Symptoms include fever, peripheral edema, weight gain more than 5 kg, pleuropericardial effusions, shortness of breath, interstitial pulmonary infiltrates, acute renal failure, and hypotension after initiating APL treatment with the differentiating agents ATRA or ATO. The diagnosis requires at least two of the above findings. Moderate DS is defined as having two to three of the above findings, whereas severe DS has four or more findings. Elevation of liver transaminases may also occur. Symptoms can develop at any time within the first 4 weeks of treatment with the highest incidence in the first and third weeks of treatment. Risk factors for the development of severe DS include WBC >5,000 per μL and elevated serum creatinine [55].

The diagnosis of DS is difficult at times as frequent complications of APL and its treatment, such as pneumonia, pulmonary hemorrhage, heart failure, acute renal failure, and sepsis, can mimic the syndrome. Early consideration of DS is important, however, so that prompt treatment with dexamethasone can be initiated. In both moderate and severe cases, dexamethasone is given at 10 mg per os (PO) or IV twice a day. Although no controlled studies of dexamethasone treatment have been published, since the inception of this practice the mortality rate from DS has dropped to less than 1% in recent studies. In moderate cases, ATRA and/or ATO can be continued safely with close monitoring for worsening symptoms. In severe cases, ATRA and/or ATO are held until symptoms resolve at which point it is generally safe to resume treatment. Administration of chemotherapy early in ATRA treatment has been shown to reduce the incidence of DS [56]. Patients with high suspicion of APL and a WBC >10,000 per μL should be treated immediately with cytotoxic chemotherapy in addition to ATRA prior to molecular diagnosis as these patients are at especially high risk of severe DS and death during
induction therapy. Even with improved recognition and treatment, 26% of patients in the LPA96 and LPA99 trials developing severe DS died during induction therapy, 11% from DS alone [55].

**Cytokine Release Syndrome**

In recent years, therapies attempting to engage T cells with target cancer cells have shown impressive activity in hematologic malignancies. The bifunctional T-cell engaging antibody blinatumomab joins anti-CD3 and anti-CD19 variable regions of monoclonal antibodies with a peptide linker to create a molecule that is able to engage T cells (through CD3) directly with CD19-expressing target cells such as B-cell lymphoblasts and B-cell lymphoma cells. Autologous T cells taken from patients and engineered to express chimeric antigen receptors composed of an extracellular short chain variable fragment of a monoclonal antibody against CD19 combined the CD3 intracellular signaling domain and a costimulatory domain are highly active against CD19-expressing malignancies such as B-cell ALL and chronic lymphocytic leukemia where response rates are approximately 90% and 45%, respectively [57].

Both of these therapies can cause a potentially fatal cytokine release syndrome (CRS) of variable severity ranging from fevers and flu-like symptoms to cardiovascular collapse requiring vasopressor support and even intubation for respiratory failure. CRS occurs with the release of cytokines such as IL-6, IFN-γ, IL-10, and others seen with robust activation and proliferation of T cells. Neurotoxicity is also frequently seen with both therapies and can manifest as encephalopathy, seizures, and neuropathies. Optimal treatment for CRS is still being defined and although corticosteroids have been used with success, the anti-IL-6 antibody tocilizumab appears particularly effective at reversing CRS [58].

**Therapeutic Agents**

Treatment of aggressive hematologic malignancies typically requires toxic, myelosuppressive chemotherapy regimens. Patients are prone to life-threatening bacterial and fungal infections as a result of prolonged neutropenia, bleeding from thrombocytopenia, and organ failure from the toxic effects of chemotherapy. Selected toxicities of agents commonly used in the treatment of hematologic malignancies and their management are given in Table 94.3.

Patients with hematologic malignancies have similar mortality to nononcologic patients when matched for disease severity.

Retrospective study of 101 consecutive ICU admissions of patients with hematologic malignancies vs. 3,808 nononcologic admissions.

Mortality of hematologic malignancy and nononcologic patients similar when matched for SAPS II score (OR = 0.59, 95% CI = 0.32–1.08, p = 0.09).

### Hyperleukocytosis

Improved short-term but not long-term survival with leukapheresis in hyperleukocytic AML.

Retrospective analysis of leukapheresis in 53 vs. no leukapheresis in 28 AML patients with hyperleukocytosis (WBC >100,000/μL).

Reduced 21-d mortality in leukapheresis group vs. no leukapheresis (16% vs. 32%, p = 0.015). No difference in overall survival (median 6.5 vs. 7.5 mo).

### Prophylactic platelet transfusion

Equivalent bleeding rates with platelet transfusion threshold 10,000/μL vs. 20,000/μL.

Meta-analysis of three prospective randomized trials.

No difference in mortality, remission rates, severe bleeding events, or RBC transfusion requirements between two threshold levels. Studies potentially underpowered.

### Noninvasive positive pressure ventilation

Improved survival with addition of noninvasive positive pressure ventilation to standard care alone in patients with early hypoxemia.

Prospective, randomized trial of 52 immunosuppressed patients with fever, pulmonary infiltrates, and early hypoxemic respiratory failure treated with NIPPV.

NIPPV superior to supplemental oxygen-based therapy alone for incidence of endotracheal intubation (2 vs. 20 patients, p = 0.03), serious
vs. supplemental oxygen-based therapy alone.

complications (13 vs. 21, p = 0.02), death in the ICU (10 vs. 18, p = 0.03), and death in the hospital (13 vs. 21, p = 0.02).

### Invasive ventilation

REFERENCES

The clinical presentation of oncologic emergencies has not changed dramatically over the past 50 years; however, the efficacy and variety of therapeutic interventions have improved considerably. Because a patient’s prognosis has a significant impact on the choice of treatments, it is of paramount importance for the intensivist and the care team to determine the following:

- Is the clinical scenario truly emergent?
- Is the syndrome related to malignancy, a side effect of treatment, or a benign process?
- What is the specific tumor type that is responsible for the syndrome?
- What is the stage of disease?
- What studies are necessary to establish the diagnosis?
- What are the wishes of the patient and family?

The prognostic implications and the expected impact of treatment are then weighed and appropriate therapy instituted or modified.

**SUPERIOR VENA CAVA SYNDROME**

**Physiology**

The superior vena cava (SVC) syndrome develops as a result of impaired
blood return through the SVC to the right atrium caused by extrinsic compression or internal thrombus. Obstruction results in venous hypertension, with the severity of ensuing signs and symptoms dependent on the site of obstruction and the rapidity with which the block occurs. The SVC is formed by the union of the left and right brachiocephalic veins in the middle third of the mediastinum and extends inferiorly for 5 to 8 cm, terminating in the right atrium (Fig. 95.1). The SVC serves as the principal venous drainage for the head, neck, and upper extremities. The major collateral, the azygous vein, joins posteriorly just over the right mainstem bronchus and drains the posterior thorax. The SVC is thin walled and is bounded by the mediastinal parietal pleura and the right paratracheal, azygous, hilar, and subcarinal lymph nodes. As a result, it is extremely susceptible to extrinsic compression by adjacent lymph nodes or the aorta, with subsequent stasis, occlusion, or thrombosis. If obstruction occurs distal to the azygous vein, collateral flow through the azygous can adequately compensate for diminished return. However, if the obstruction is proximal to the azygous, flow must completely bypass the SVC and return via internal mammary, superficial thoracoabdominal, and vertebral venous systems to the inferior vena cava. This more circuitous route results in significantly higher venous pressures, which can result in interstitial edema of the head and neck as well as extrinsic compression of the larynx or trachea.

Etiology

The vast majority of patients with the SVC syndrome have bronchogenic carcinoma, most commonly of the small cell histology (Table 95.1). Non-Hodgkin lymphoma, breast cancer, and other neoplasms make up the remainder of the malignant causes. Despite a high frequency of mediastinal involvement, Hodgkin lymphoma patients rarely present with SVC compression. Benign causes of SVC syndrome exist in up to 40% of all cases and include thrombosis due to indwelling intravenous catheters or fibrosing mediastinitis from infectious causes [1].

Clinical Manifestations

The presentation of SVC syndrome depends largely on the acuity of the obstruction to flow. In patients with benign causes, extensive collateral flow often develops that minimizes symptoms for months to years. Acute compression by tumor or thrombosis does not allow time for collateralization, and venous hypertension inevitably results in symptoms, which include dyspnea, cough, dysphagia, and edema of the face, neck, upper torso, and extremities. Physical signs include jugular venous distention, edema of the face or upper extremities, dilated venous collaterals, plethora, stridor, and tachypnea. Rarely, SVC syndrome can lead to the serious sequela of cerebral edema resulting in headaches, confusion, and possibly coma.

Diagnosis

Initial evaluation should include a chest radiograph and contrast-enhanced computed tomography (CT) to confirm the clinical diagnosis, identify a potential etiology, and localize the obstruction. Venography or magnetic resonance imaging (MRI) may be appropriate in subsequent evaluation to better define the extent of obstruction, particularly if stenting of the obstruction is considered (Fig. 95.2). Of note, focal hepatic contrast enhancement on CT has been noted in patients with SVC syndrome due to collateralization through patent remnants of the umbilical vein or of the musculophrenic venous system [2]. These abnormalities could be mistaken for metastatic disease and should be further evaluated in patients in whom therapy would be changed in the presence of isolated metastases. If a malignant cause of SVC obstruction is considered, all reasonable efforts should be made to obtain diagnostic material, as treatment depends on the underlying histology. The approach may include sputum cytology, bronchoscopy using endobronchial ultrasound-guided needle aspiration, transthoracic needle aspiration, biopsy of palpable lymph nodes, mediastinoscopy, thoracotomy, or video-assisted thoracoscopy. Despite concerns regarding surgical complications, morbidity associated with surgical procedures necessary to procure a diagnosis is not substantially different from that in patients without the SVC syndrome [3]. With rare exceptions, it is safe to wait to institute treatment until the underlying cause of the syndrome has been established. Clinicians at Yale University have proposed a grading scheme for severity of SVC syndrome spanning from asymptomatic to life threatening based on the presence of significant cerebral edema, laryngeal edema, or hemodynamic compromise. They estimated that life-threatening symptoms requiring immediate intervention prior to diagnostic evaluation occur in only 5% of cases of SVC syndrome [4].
Treatment

Once the diagnosis is established, initiation of therapy depends on the etiology, the severity of symptoms, the acuity of presentation, and the goals of treatment. If patients are minimally symptomatic, the azygous is patent, and treatment is focused on palliation, observation is a reasonable option. Chemotherapy is the treatment of choice for SVC syndrome due to small cell lung carcinoma, non-Hodgkin lymphoma, and germ cell tumors. Although radiation is often considered in addition to chemotherapy even in the palliative setting, 80% of these patients have a complete or partial response of their symptoms to chemotherapy alone [5]. Other histologies should be treated with endovascular stent placement, radiation therapy, or both. Radiation therapy prior to biopsy has been associated with a significant reduction in rates of histologic diagnosis and should be avoided [6]. Although external beam radiation effectively palliates symptoms in more than 70% of patients within 2 weeks [7], relapse after radiotherapy occurs in 15% to 30% of cases.

Endovascular stent placement, as a primary intervention, is a particularly attractive option for patients who lack a tissue diagnosis and whose symptoms on presentation require a rapid palliative intervention; this includes all patients, regardless of histology, who present with airway compromise or cerebral edema. SVC stent placement can provide rapid relief of symptoms (within 48 hours of placement) in up to 95% of patients with a primary patency rate of 80% at 6 months [8].
authors have suggested a role for stent placement for first-line management of all SVC syndrome patients as outcomes are encouraging with low rates of complications, but no randomized controlled trials have been published [9]. Anticoagulation after stent placement is controversial with recent publications advocating the use of antiplatelet agents such as aspirin for 3 to 6 months following insertion [8,9].

In patients with an established diagnosis, radiation therapy remains an appropriate intervention. Many fractionation protocols have been used, with the majority of patients receiving 30 Gy in 10 fractions, whereas patients treated with curative intent often receive 50 Gy in 25 fractions. Although high doses of radiation have often been given early in the treatment course to achieve rapid tumor response, there is little evidence to suggest that this is necessary [10]. In cases of SVC thrombosis with an indwelling catheter or pacemaker, thrombolytic agents may be useful as primary therapy or as an adjunct to stent placement [11]. The additional benefit of thrombolytics or anticoagulation in patients treated for malignant SVC syndrome is not well established.

Surgical resection and reconstruction of the SVC is reserved for patients with benign disease or the rare patient with tracheal obstruction in the setting of chemotherapy or radiotherapy-resistant disease.

SVC syndrome has been thought to predict poor outcomes. However, the presence of SVC syndrome is not a negative prognostic factor in small cell carcinoma and lymphoma independent of the stage and bulk of disease, and patients should be treated with curative intent if otherwise appropriate [12].
CARDIAC TAMPONADE

Physiology

Cardiac tamponade results from accumulation of fluid within the pericardium that impairs left ventricular expansion and diastolic filling. As stroke volume drops, compensatory tachycardia occurs to offset progressive hypotension. Ultimately, pressures equalize in the left atrium, pulmonary vasculature, right atrium, and SVC, and circulatory collapse ensues. As with SVC syndrome, the severity of symptoms is dependent on the speed of progression. Tamponade occurs when the pericardium cannot expand with resultant impedance to venous inflow.

Etiology

Malignancy is identified as the cause in up to 40% of unselected patients presenting with cardiac tamponade; the frequency with which tamponade develops as the initial manifestation of the patient’s disease has led to standard cytologic examination of all significant effusions [13,14]. Tumors may involve the pericardium by direct extension from intrathoracic organs or hematogenous spread. Malignancies most often associated with pericardial effusions are lung, breast, lymphoma, and leukemia. Pericardial effusions in patients with cancer are due to pericardial or cardiac involvement in 60% of cases, with idiopathic pericarditis and radiation-induced pericarditis causing 32% and 10% of cases, respectively [15].

Clinical Manifestations

Common symptoms of pericardial effusion include dyspnea (85%), cough (30%), orthopnea (25%), and chest pain (20%). The common signs of pericardial effusion are jugular venous distention (100%), tachycardia (100%), pulsus paradoxus (89%), systolic blood pressure of less than 90 (52%), and pericardial friction rub (22%) [16]. Plain films may demonstrate cardiac enlargement in at least half of all cases, and electrocardiography may reveal abnormalities suggestive of pericarditis (low-voltage, ST-segment elevation) or electrical alternans.

Diagnosis

Echocardiography is the most useful means of rapidly detecting a hemodynamically significant effusion. The echocardiographic findings of
pericardial tamponade are reviewed in Chapter 17 (Pericardiocentesis). Echocardiography also allows estimation of the volume, fluidity, and contents of the effusion, although it is difficult to distinguish tumor, thrombus, or fibrinous material from one another. Emergent treatment of tamponade invariably involves drainage of the effusion, and cytologic evaluation of the fluid provides a very specific means of establishing a malignant etiology. The detection rate for malignancy by pericardial fluid cytology ranges from 66% to 90%, and certain histologies, such as lymphoma and mesothelioma, are more difficult to demonstrate in pericardial fluid [17,18]. Hemorrhagic effusions are more likely to be related to malignancy [17]. Pericardial biopsy is occasionally required to establish a diagnosis in difficult cases and can be performed under local anesthesia using a subxiphoid approach.

**Treatment**

Cardiac tamponade requires immediate treatment to relieve the increased end-diastolic pressure and inadequate ventricular filling. Oxygen, pressor agents, and intravenous fluids to improve cardiac output should be provided as appropriate. Inotropic agents are frequently ineffective, however, because a state of intense adrenergic stimulation is already present [19]. When airway management is required, significant caution should be exercised because the positive intrathoracic pressure that results from initiation of mechanical ventilation places tamponade patients at particularly high risk of profound post-intubation hypotension [19]. Emergent pericardiocentesis is indicated for significant hypotension, and it has been suggested that a pulse pressure of less than 20 mm Hg, a paradoxic pulse greater than 50% of the pulse pressure, or a peripheral venous pressure above 13 mm are other absolute indications for emergent intervention [20]. Because of the high rate of recurrent effusions after a simple pericardiocentesis in patients with tamponade from malignancy, additional therapy is generally indicated. One option is to perform a pericardiostomy (pericardial window) via a surgical approach or a balloon catheter to drain the pericardial fluid. In one retrospective study that compared outcomes of 118 patients undergoing simple pericardiocentesis alone to 18 patients undergoing pericardiocentesis followed by pericardial surgery, the patients in the former group had a recurrence rate of 36% whereas none of the patients in the latter group had recurrence [21]. A recent retrospective multicenter study also suggested that patients had superior outcomes when systemic chemotherapy was combined with a pericardiostomy rather than simple pericardiocentesis or pericardial drainage [22].

Radiation therapy is noninvasive and allows treatment of the majority of the pericardium but carries a theoretical risk of radiation-induced
pericarditis. As a single modality, radiation controls pericardial effusion in 67% of cases, with a particularly high success in hematopoietic tumors (93%) [23]. Systemic therapy is generally used only for diseases that are considered to be chemosensitive, such as breast cancer or lymphoma; in these individuals, it prevented recurrence in 73% of treated patients[23].

Instillation of sclerosing agents, radionuclides, and chemotherapy through indwelling catheters has been widely used with the intent to induce nonspecific inflammation with obliteration of the pericardial space or to achieve specific antineoplastic effects. Typically, a catheter is placed into the pericardial sac and drainage continued until output is less than 100 mL per day. Sclerosing agent or chemotherapy is injected into the catheter every 24 to 48 hours until fluid output is less than 25 to 50 mL per day, and the catheter is removed. A review of 20 different studies reported an overall control rate of 82% with common toxicities, including fever, pain, arrhythmias, and occasional cytopenias [23]. A wide variety of agents have been used including tetracycline, doxycycline, minocycline, bleomycin, and talc. However, use of sclerosing agents has not shown a definitive benefit over drainage alone and this technique is used infrequently [24].

Prognosis

The development of malignant pericardial effusion and tamponade usually reflects uncontrolled metastatic disease and portends a dire prognosis. Median survivals for patients treated for tamponade range from 2 to 4 months [25]. Nonrandomized studies suggest that patients with hematologic malignancies and breast cancer have substantially better survival rates if systemic therapy can be instituted [26,27]. The decision to intervene in a patient with malignant cardiac tamponade depends on the patient’s histology and sensitivity to treatment as well as the patient’s condition. Patients for whom treatment of tamponade provides meaningful palliative benefit should be considered for the treatment that is likely to provide durable relief of symptoms with the minimum of morbidity and requirement for hospitalization.
MALIGNANT EPIDURAL CORD COMPRESSION

Few complications of malignancy are more dreaded than epidural cord compression. The associated pain, neurologic deficits, and dramatically impaired quality of life are serious problems for the patients who develop this condition and by extension, for their families. Early recognition of the signs and symptoms of cord compression may prevent serious compromise in survival and functional capacity. Epidural cord compression is defined by compression of the dural sac and its contents by an extradural tumor mass. Minimum radiologic evidence for compression is indentation of the theca at the level of clinical features, which include pain, weakness, sensory disturbance, or evidence of sphincter dysfunction [28]. Approximately 20% of cases are the initial manifestation of malignancy [29].

Physiology

Epidural cord compression by malignancy occurs as a result of metastasis or primary tumor involvement of the vertebral column, paravertebral space, or epidural space. Damage to the cord occurs when the tumor compromises the vertebral venous plexus or compresses neural tissue directly or when compromised bone impinges on the cord. The resulting vasogenic edema and hemorrhage induce further ischemic damage. The vertebral body is the most common source of compressive lesions, predominantly in the thoracic (60%), followed by the lumbar (25%) and cervical (15%) regions [30]. Tumor invasion through the intervertebral foramen and cord compression without bone involvement is most often seen with lymphoma, leading to normal plain films and radionuclide scans despite clinical compression. Multiple noncontiguous levels are involved in 10% to 40% of cases [31].

Etiology

The most common causes of malignant cord compression are tumors with a propensity for bony metastasis, including breast and lung, followed by hematopoietic, gastrointestinal, and genitourinary malignancies [32] (Table 95.2). Nonmalignant causes of cord compression include stenosis, epidural abscess, or hematoma.

**TABLE 95.2 Primary Diagnosis**
Clinical Manifestations

The cardinal sign of malignant cord compression is pain, present in 95% of patients at diagnosis. The median time from pain onset to a diagnosis of cord compression is approximately 2 months. Pain is typically worse with recumbency, coughing, straining, or exercise. Radicular pain develops later and is an important localizing sign. Weakness, autonomic dysfunction, and sensory changes are present in more than 50% of cases [30]. Isolated bowel or bladder dysfunction is rarely the presenting symptom of cord compression; however, 50% to 60% of patients can have bowel or bladder symptoms at the time of diagnosis ranging from urgency to incontinence or retention, which can indicate more severe cord involvement [30].

Diagnosis

The diagnosis of cord compression relies primarily on MRI, given its sensitivity, speed, and the ability to detect compression at multiple levels. MRI allows evaluation of the entire spine including vertebral bones and soft tissues in the paravertebral space. It has a sensitivity and specificity of 93% and 97% respectively in detection of cord compression [33]. Other imaging techniques including plain films and radionuclide bone scans can be used but cannot match the accuracy of MRI. A prospective study
analyzed the expected outcome with treatment planning on the basis of plain films and clinical examination versus use of MRI, and found that MRI changed the radiotherapy plan in 53% of patients [34]. These changes included 21% of patients in whom all paraspinal disease would not have been treated and 5% of those in whom additional levels of true cord compression would not have been treated. In 30% of patients, the demonstrated level of compression on MRI was more than two vertebral levels away from the level indicated by neurologic examination. If patients are unable to undergo MRI because of claustrophobia, the presence of metal implants, or access, myelography can be performed instead. CT scanning is superior to MRI for definition of vertebral body anatomy and may be useful before consideration of surgical intervention.

**Treatment**

Therapeutic options include corticosteroids, surgery, and radiation. In emergent situations, corticosteroids are generally given while awaiting MRI to decrease peritumoral edema and to prevent edema formation during radiation. On the basis of laboratory studies and a single randomized controlled trial that compared high-dose dexamethasone with radiation to radiation alone, some authors support the use of high-dose dexamethasone, defined as a 96-mg intravenous bolus followed by 96 mg per day tapered over a 2-week period [35]. A reasonable alternative is a moderate dose approach with a 10-mg intravenous loading dose followed by 4 mg every 6 hours tapered over 2 weeks [36], especially in patients who are clinically stable. Ambulatory patients without progressive deficit may forgo steroids altogether during radiotherapy without undue risk [37].

Historically, radiation therapy and direct decompressive surgery were felt to be equally effective as initial interventions in patients with metastatic spinal cord compression. However, a randomized trial published in 2005 compared direct decompressive surgery plus postoperative radiotherapy to radiotherapy alone, demonstrating a statistically significant outcome benefit to the combined approach for patients who had less radiosensitive tumors and only one area of spinal cord compression [38]. Compared with patients who received radiotherapy alone, more patients who underwent surgery were able to walk after treatment (84% vs. 57%) and were ambulatory for a significantly longer duration (median: 122 vs. 13 days). First-line radiation therapy remains an important option for patients with
radiosensitive tumors, nonsurgical candidates, patients with multiple areas of spinal cord compression, and those who experienced symptoms of total paraplegia for longer than 48 hours at presentation. Because surgical complication rates approach 20%, radiation therapy should generally be used as the first-line intervention in patients over age 65 [39]. Specific radiation treatment plans for cord compression vary between centers. In patients with metastatic spinal canal compression, a single fraction of 8 Gy can effectively improve neurologic function and treat pain [40].

Prognosis

Early intervention is vital to preserving function. For patients who are ambulatory at the time of treatment, at least 80% remain ambulatory. The development of paraparesis decreases the ambulation rate to 50%, and patients who are paraplegic at the time of therapy recover ambulation only 10% to 19% of the time after radiation therapy alone [38,41]. In paraplegic patients, outcomes appeared to be better for individuals who were candidates for upfront surgical decompression (62% of patients randomized to combined surgery plus radiation regained the ability to walk compared with 19% of those who received radiation alone), the difference was statistically significant, but the sample size was small (n = 32) [38].
HYPERCALCEMIA

Hypercalcemia of malignancy (HCM) is the most common emergent metabolic disorder associated with cancer, affecting 20% to 30% of patients with malignancy at some time during their clinical course [42]. Although hypercalcemia has been associated with nearly all malignancies, it is most frequently associated with multiple myeloma, breast, lung, and kidney cancers.

Physiology

In healthy persons, vitamin D and parathyroid hormone (PTH) control absorption and mobilization of calcium. Calcitriol, the active form of vitamin D, enhances gastrointestinal absorption and mobilizes calcium from bone. PTH increases renal calcium resorption in the distal tubule and also mobilizes calcium from bone. In patients with HCM, increased calcium mobilization combines with renal insufficiency to cause symptomatic hypercalcemia. At least two mechanisms are proposed: direct osteolysis by tumor or increased osteoclastic resorption as a result of humoral mediators such as PTH-related protein (PTHrP), calcitriol, and PTH. Both mechanisms may be active in many patients.

PTHrP is postulated to play a role in the majority of patients with HCM, as levels are elevated in at least 80% of cases [43]. PTHrP is a normal gene product expressed in a variety of tissues and it appears to have important roles in calcium transport and developmental biology. The N-terminal 13 amino acids of PTHrP share amino acid sequence and homology with intact PTH and it can bind to PTH-1 receptor leading to hypercalcemia when pathologically secreted in excess by cancer cells. PTHrP stimulates osteoblasts to produce receptor activator of nuclear factor-κ B ligand (RANKL) which in turn activates osteoclast precursors and leads to both osteolysis and the release of bone-derived growth factors. These growth factors, including transforming growth factor-β and insulin like growth factor-1, are known to both promote tumor cell proliferation and further increase production of PTHrP [44]. Circulating vitamin D metabolites may be increased in some lymphomas, enhancing intestinal calcium absorption and causing or exacerbating hypercalcemia [45].

Normal kidneys are capable of filtering and excreting four to five times the normal calcium concentration in the serum to maintain serum calcium homeostasis. PTHrP increases renal tubular resorption and osteolytic calcium release, causing rapid and persistent elevation of extracellular calcium. The subsequent calciuria and osmotic diuresis
result in volume depletion. Decreased glomerular filtration limits the kidney’s ability to filter and excrete calcium, and proximal tubular calcium and sodium reabsorption increase, leading to further increases in serum calcium concentrations. Symptoms of nausea and vomiting worsen the dehydration. If the concentration of calcium in the glomerular filtrate exceeds its solubility, calcium may precipitate in the renal tubules, further compromising renal function.

The direct osteolytic effect of tumors leads to hypercalcemia in about 20% of cases; and this phenomenon is seen most frequently in breast cancer, multiple myeloma, and lymphomas. In rare cases, tumors can secrete calcitriol or PTH leading to hypercalcemia.

Etiology

HCM occurs most frequently in patients with breast cancer, multiple myeloma, and squamous cell malignancies of the lung, head and neck, and esophagus. Some malignancies are rarely associated with hypercalcemia despite a propensity for widespread metastases, including prostate cancer and small cell lung cancer. A recent case series of 138 cases of PTHrP-mediated hypercalcemia identified squamous cell lung cancer as the single most common etiology (10.9%) followed by urothelial carcinoma (8.7%), other non-small cell lung cancers (8.7%), adenocarcinomas of unknown primary (8.0%) and breast cancer (7.2%) [46].

Clinical Manifestations

As with other oncologic emergencies, the rapidity with which hypercalcemia develops often determines the severity of symptoms. Some patients may have significant symptoms with minimally elevated calcium and require therapy, whereas other patients are minimally symptomatic despite long-standing hypercalcemia. Many of the symptoms of hypercalcemia are relatively nonspecific, and the possibility of hypercalcemia must be kept in mind when considering patients with nausea, fatigue, lethargy, and mental status changes. Decreased intravascular volume and hypercalcemia cause malaise, fatigue, anorexia, and polyuria. Hypercalcemia decreases neuromuscular excitability and decreased muscle tone. Neuromuscular symptoms include weakness and diminished deep tendon reflexes. Neuropsychiatric manifestations may include confusion, lethargy, psychosis, or even coma. Hypercalcemia heightens cardiac contractility and irritability, and this is reflected by
electrocardiographic changes, such as prolonged PR interval, widened QRS complex, and a shortened QT. With progressive hypercalcemia, bradyarrhythmias and bundle-branch block may develop, which can evolve to complete heart block and asystole.

**Diagnosis**

The diagnosis of hypercalcemia is documented by the presence of elevated corrected serum calcium, defined by the following formula:

\[
[4.0 - \text{patient (Alb)}] \times 0.8 + [\text{Ca}],
\]

where Alb signifies albumin. Alternatively, an elevation of serum ionized calcium documents hypercalcemia and does not require the concomitant measurement of serum albumin. Other laboratory studies that should be considered include PTH, PTHrP, blood urea nitrogen and creatinine, phosphate, and magnesium. The assessment of a patient presenting with hypercalcemia should include several important aspects of disease history. Although hypercalcemia is a common complication of malignancy, other nonmalignant causes (including hyperparathyroidism, intravenous fluids, total parenteral nutrition, milk-alkali syndrome, thiazide diuretics, vitamins A and D, and lithium) are present in 10% to 15% of cancer patients who present with hypercalcemia and should be considered in the differential diagnosis.

**Treatment**

The decision to treat hypercalcemia should be dictated by the patient’s history, current disease status, quality of life, and the wishes of the patient and family. The prognosis for most patients with HCM is poor with the median overall survival reported at 52 days from one case series [46]. Severe pain, obstruction, or irreversible structural symptoms may be an indication not to pursue therapy. However, relief of the symptoms of hypercalcemia may improve quality of life and functional status for many patients during the remainder of their lifetimes. Patients who are symptomatic and who have no other potential etiology of hypercalcemia should be treated. If calcium is elevated but the patient is asymptomatic, specific hypocalcemic therapy can be held, with close observation, particularly if effective systemic therapy is to be initiated. Because most symptoms and the underlying physiology of hypercalcemia are due in part to volume depletion, intravenous hydration is the initial therapy of choice (Table 95.3). Although no randomized controlled clinical trials have been conducted to inform the approach to hydration, in general patients require repletion with 3 to 7 L intravenous saline over 24 to 36 hours to achieve euvoolemia. If congestive heart failure is a concern or if the patient has severe hypercalcemia, loop diuretics can be used, but only
after it is clear that adequate volume expansion has been achieved. If diuretics are used before the glomerular filtration rate has been restored, renal clearance of calcium is impaired further, and hypercalcemia may worsen despite the best intentions. Loop diuretics suppress proximal absorption of sodium and calcium, augmenting calciuresis.

Alternatives: prednisone, denosumab, dialysis

Bisphosphonates are the most useful hypocalcemic agents available for controlling HCM. They inhibit prenylation of small guanosine triphosphatases, which are necessary for osteoclast function and are cytotoxic to osteoclasts through a number of different mechanisms [47]. Zoledronic acid and pamidronate are the bisphosphonates currently in clinical use. Two randomized trials comparing pamidronate and zoledronic acid demonstrated improved response rates for zoledronic acid, 4- and 8-mg infusions; complete response rates by day 10 were
88.4%, 86.7%, and 69.7% for zoledronic acid, 4 and 8 mg, and pamidronate, 90 mg, respectively [48]. Normalization of calcium occurred by day 4 in 50% of patients treated with zoledronic acid and 33% of those given pamidronate. Median duration of complete response favored zoledronic acid, 4 and 8 mg, over pamidronate, with response durations of 32, 43, and 18 days, respectively. Optimal zoledronic acid dosage and administration schedules have not been established; the standard dose is 4 mg, with 8 mg reserved for patients with recurrent or refractory hypercalcemia. The onset of zoledronic acid’s effect is apparent within 3 to 4 days, with maximal effect within 7 to 10 days, and lasts for 14 days to 2 months. Adverse effects include transient low-grade temperature elevations that typically occur within 24 to 36 hours after administration and persist for up to 2 days (≤20% of patients). New-onset hypophosphatemia and hypomagnesemia may occur; preexisting abnormalities in the same electrolytes may be exacerbated by treatment. Serum calcium may fall below the normal range, although symptoms are rare. Acute kidney injury has been reported with zoledronic acid, and renal function should be monitored routinely during administration [49].

A relatively uncommon but potentially serious side effect of bisphosphate treatment is osteonecrosis of the jaw, a form of avascular necrosis. The overall risk of this complication is <2%, and the risk is significantly increased in individuals with underlying dental conditions or those undergoing dental procedures during treatment.

Other treatments for HCM include corticosteroids, calcitonin, and denosumab. Calcitonin rapidly inhibits bone resorption and decreases renal calcium reabsorption. Salmon calcitonin is administered at 4 IU per kg subcutaneously or intramuscularly every 12 hours, and tachyphylaxis occurs rapidly, necessitating dosing increases to 8 IU every 6 to 12 hours. Efficacy is limited to the first 24 to 48 hours after initiation of therapy, and additional treatment with bisphosphonate should be considered concurrent with calcitonin. Corticosteroids are effective in lymphoma and multiple myeloma, tumors in which steroids are often cytotoxic. The onset of action is slow, over several weeks, and the mechanism of effect is through treatment of the underlying malignancy and suppression of gastrointestinal calcium absorption. Therapies designed to interfere with RANKL binding, including the monoclonal antibody denosumab and a decoy RANKL receptor, osteoprotegerin, appear to decrease serum calcium levels in preclinical and clinical settings; however, no randomized clinical trials have been performed to evaluate these agents in patients with hypercalcemia. Denosumab may have a role in the
treatment of HCM that is refractory to bisphosphonates or in patients with renal dysfunction as unlike bisphosphonates, it is not cleared by the kidneys [50,51]. Dialysis should be considered for patients with severe renal insufficiency and associated electrolyte abnormalities, particularly in patients for whom effective therapy is available.

Hypercalcemia reflects biologically aggressive, advanced disease. For patients with solid tumors, particularly those with chemotherapy-resistant disease, the prognosis is extremely grim, with median survivals of 30 to 60 days in most studies [52]. By contrast, hypercalcemia in patients with multiple myeloma and breast cancer is associated with relatively longer survival. The argument has been made that treatment of HCM prolongs survival in patients in whom other morbid complications of their disease will develop. In fact, it is clear that hypocalcemic agents do not prolong survival but can have impressive palliative benefit in relieving symptoms from hypercalcemia, such as nausea, emesis, and constipation, and improving pain control for some patients who achieve normocalcemia.
LEUKOSTASIS

Physiology

Leukostasis is a potentially devastating complication of leukemia in patients who present with hyperleukocytosis, defined as a leukocyte count greater than 100,000 per μL. The syndrome of leukostasis is related to obstruction of flow in capillary beds of the central nervous system, lungs, and heart by immature, rigid blasts. Although viscosity might be expected to play a role, it is rarely elevated because the principal determinant of viscosity, red blood cells, is often low due to marrow replacement by leukemic blasts. The obstruction of capillary beds by blasts and restricted flow results in tissue hypoxia, cytokine release, and coagulation. Tissue invasion also occurs and is not affected by leukapheresis. The risk of leukostasis was evaluated by Lichtman and Rowe [53], who demonstrated that the leukocrit, which is proportional to the number and volume of circulating leukocytes and blasts, was the parameter most closely associated with the development of leukostasis.

Etiology

Hyperleukocytosis occurs in 10% to 20% of patients with acute myelogenous leukemia (AML) at presentation and is much less common in patients with chronic myelogenous leukemia, acute lymphoblastic leukemia, or chronic lymphocytic leukemia. For equivalent degrees of leukocytosis, the risk of leukostasis is much higher with AML than with other diagnoses because of the larger size and adhesion characteristics of AML blasts. The risk of developing leukostasis depends on total white blood cell count, the percentage of blasts, and the rate at which counts are rising. The clinical presentation, diagnosis, and management of hyperleukocytosis are discussed in further detail in Chapter 94 and apheresis treatment in Chapter 96.
HYponatremia

Physiology

Clinically symptomatic hyponatremia is a relatively rare complication of malignancy affecting only 1% to 2% of cancer patients. In the majority of these individuals, the syndrome of inappropriate antidiuretic hormone (SIADH) develops. Secretion of ectopic ADH occurs almost solely in patients with small cell bronchogenic carcinoma, and the majority of other patients have coincident central nervous system or pulmonary disease. As a result of excess ADH, excessive water resorption occurs in the collecting ducts, and extracellular fluid osmolality decreases inappropriately. Water is able to move freely, and the decrease in extracellular osmolality results in a shift to the intracellular compartment with associated cellular edema. When hyponatremia occurs acutely, this edema causes dramatic neuronal edema and subsequent neurologic symptoms. Plasma volume expands, and urinary sodium excretion parallels the rate of oral sodium intake. Typically, the patient with SIADH is euvoletic to slightly hypervolemic, urine sodium is greater than 20 mEq per L, and plasma urea, uric acid, creatinine, and rennin activity are normal or low.

Etiology

Hyponatremia occurs most frequently in small cell lung cancer with approximately 25% of patients noted to have a serum sodium of <136 mEq per L [54]. SIADH has also been reported in a broad variety of other malignancies but is most commonly found in the setting of central nervous system or pulmonary metastases. SIADH may also develop in patients with malignancy because of other conditions, including the use of opiates, vinca alkaloids, β agonists, chlorpropamide, and cyclophosphamide. Hypoadrenalism caused by rapid tapering of therapeutic corticosteroids is another common etiology for mild hyponatremia. Other etiologies include volume contraction resulting from emesis or diarrhea, renal wasting resulting from diuretics or intrinsic renal disease, and pseudohyponatremia resulting from excess serum lipids or paraproteins. Hypothyroidism and pulmonary or central nervous system disease are also potential causes of SIADH.

Diagnosis

Hyponatremia is often manifested as fatigue, nausea, myalgia, headaches,
and subtle neurologic symptoms. Rapid drops in serum sodium or levels less than 115 mg per dL cause altered mental status, seizures, coma, pathologic reflexes, and papilledema. The diagnostic evaluation includes a review of medications and assessment of volume status as well as serum and urine electrolytes, osmolality, and creatinine. Patients with SIADH have inappropriately elevated urine sodium, and urine osmolality is greater than plasma osmolality but never reaches maximal dilution (<100 μ Osm per L). Thyroid and adrenal dysfunction cause similar electrolyte imbalances and must be ruled out if laboratory studies suggest SIADH. CT or radiographs of the chest and brain may be necessary to eliminate pulmonary or central nervous system disease as causes of excessive ADH secretion.

Treatment

Treatment of the hyponatremia is tailored to the time course of its development and the extent of symptoms that the patient is experiencing. Asymptomatic hyponatremia can be managed with fluid restriction alone. Treatment of the underlying malignancy may alleviate SIADH due to small cell carcinoma. Local therapy to brain or pulmonary metastases may improve serum sodium, and discontinuing offending medications should be effective. Acute symptomatic hyponatremia can be treated as indicated in Table 95.4.

Free water restriction is expected to improve hyponatremia within 7 to 10 days. Demeclocycline induces a dose-dependent, reversible nephrogenic diabetes insipidus and is expected to correct sodium within 3 to 4 days. The primary side effect of demeclocycline is renal toxicity,
and the risk of toxicity is increased by renal or hepatic dysfunction. The initial dose of demeclocycline is 600 mg daily to a maximum of 1,200 mg per day in two- to three-times-a-day dosing. Unfortunately, this approach is only effective in approximately 60% of patients [55]. Tolvaptan is an oral vasopressin receptor antagonist approved for the treatment of euvolemic or hypervolemic hyponatremia, and does not require severe fluid restriction. It increases urine water excretion by blocking the effects of endogenous vasopressin in the renal collecting duct. The starting dose is 15 mg per day and close monitoring in a hospital setting is required to ensure that serum sodium is corrected in a controlled manner. Patients should be provided access to sufficient amounts of water to ensure that they do not become overly dehydrated [56]. A small case series has demonstrated efficacy in patients with SIADH from small cell lung cancer [57]. Conivaptan is an intravenous vasopressin receptor antagonist, which also has demonstrated efficacy in SIADH.

Patients who are seizing, comatose, or rapidly decompensating should be treated with hypertonic saline and furosemide to induce an isotonic diuresis as originally proposed by Gross et al. [58] and Hantman et al. [59]. Once the sodium level is above 120 mg per dL, more conservative measures are appropriate. The primary risk of rapid correction of hyponatremia is central pontine myelinolysis, which typically occurs 3 to 5 days after repletion with corticobulbar spinal dysfunction, dysphasia, quadriplegia, and delirium. Although controversial, most data support the idea that the risk of pontine myelinolysis is greatest for patients with chronic, severe hyponatremia who are treated too rapidly. Generally, the sodium level should not be corrected at a rate faster than 6 mEq per L within 6 hours even in acute circumstances.
ONCOLOGIC THERAPEUTICS

Chemotherapeutic and supportive care agents may themselves lead to toxic effects that require critical care. Potentially offending agents, and the physiologic impact, are summarized in Table 95.5.

**Tretinoin**

Differentiation syndrome

- Presents with unexplained fever, weight gain, peripheral edema, dyspnea with pulmonary infiltrates, pleuropericardial effusion, hypotension, acute renal failure
- Prophylaxis/preemptive approach may include use of prednisone, methylprednisolone, or dexamethasone
- Occurs more frequently with higher disease burden

Ig, immunoglobulin; IVIG, intravenous immunoglobulin; IFN, interferon; IL, interleukin; TNF, tumor necrosis factor.
TUMOR LYSIS SYNDROME

Physiology

Tumor lysis syndrome (TLS) is a metabolic emergency that remains a significant risk for patients with hematopoietic malignancy and is being recognized with greater frequency in patients with solid tumors. TLS results from the release of intracellular purines, phosphate, and potassium from rapidly proliferating tumor cells, which may occur spontaneously or with the initiation of therapy. The massive tumor necrosis that initiates the syndrome may occur as a result of tumor hypoxia or with the use of chemotherapy, radiation, or embolization of tumor. Tumor lysis is followed by hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcemia, and renal insufficiency. Hyperuricemia, combined with metabolic acidosis, results in crystallization of uric acid in the collecting ducts of the kidneys and ureters, leading to obstructive uropathy. Hyperphosphatemia may also cause metastatic calcification in the renal tubules. The resultant renal insufficiency worsens hyperkalemia and hypocalcemia.

Etiology

Patients at highest risk include those with Burkitt lymphoma, bulky, aggressive non-Burkitt non-Hodgkin lymphoma, and acute leukemia presenting with an initial leukocytosis greater than $100 \times 10^9$ per L [60]. The frequency of TLS depends on the criteria used, which are not well established or accepted. New agents in CLL have also been associated with high rates of tumor lysis syndrome including ibrutinib and venetoclax. In Burkitt lymphoma, the incidence may be as high as 30%, and in patients with acute leukemia with hyperleukocytosis, electrolyte disturbances develop consistent with TLS in 50% of cases [61,62]. A variety of solid tumors have been reported to cause the syndrome, but the most common appear to be small cell lung carcinoma, germ cell tumors, and neuroblastoma [60]. Generally, these malignancies are clinically aggressive and sensitive to chemotherapy or radiation. The International Tumor Lysis Syndrome consensus panel also recommends incorporating renal function into risk assessment by classifying low-risk patients as intermediate risk and intermediate-risk patients as high risk if there is evidence of renal dysfunction, renal involvement, or elevated uric acid, phosphate, or potassium at presentation [60].

Diagnosis
The diagnosis of TLS is a clinical one, as there is no specific pathognomonic finding or laboratory value that is specific to the syndrome. The diagnosis of TLS is made on the basis of the presence of azotemia, hyperuricemia, hyperphosphatemia, and hypocalcemia in a patient with extensive, rapidly proliferating tumor. Profound metabolic acidosis out of proportion to the degree of renal insufficiency is common. Many of the metabolic abnormalities of TLS may occur as a result of acute renal failure alone, and a urinary uric acid to creatinine ratio greater than 1 helps to distinguish acute uric acid nephropathy from other catabolic forms of acute renal failure.

**Treatment**

Management can be grouped into prevention/conservative therapy and hemodialysis. Allopurinol in doses of 200 to 600 mg/m²/d should be initiated before therapy to decrease uric acid production [63]. Intravenous allopurinol can be used for patients who are unable to take oral allopurinol. Allopurinol is associated with a significant number of side effects and should be discontinued within 3 days of completion of treatment if there is no evidence of tumor lysis. Intravenous hydration of 2 to 3L/m²/d should be given with close monitoring of urine output with a target of 2 mL/kg/h [63]. Urinary alkalinization is controversial and it is recommended only in patients with metabolic acidosis [63]. Hyperkalemia should be aggressively managed with potassium restriction and sodium polystyrene sulfonate as appropriate. Hemodialysis is often necessary and is indicated to control volume, reduce phosphorus and uric acid levels, and manage uremia. Some proposed criteria for initiation of hemodialysis are persistent hyperkalemia despite conventional treatment, rapidly rising phosphate, symptomatic hypocalcemia, fluid overload, severe metabolic acidosis, and hyperuricemia. Typically, daily dialysis is necessary because the catabolic rate is sharply increased in patients with TLS. Daily weights, close monitoring of fluid intake and output, and serum electrolytes, including potassium, calcium, phosphorus, and uric acid, should be performed at least twice a day in a patient at high risk and more frequently if dialysis is instituted.

Rasburicase is a recombinant urate oxidase that converts uric acid to more soluble allantoin. A randomized study of rasburicase and allopurinol in pediatric patients at high risk of tumor lysis demonstrated that uric acid levels were substantially lower in patients receiving prophylactic rasburicase. The size of the trial was too small to demonstrate a significant difference in renal failure, and the incidence of tumor lysis was not reported [64]. A phase III study compared rasburicase alone to rasburicase plus allopurinol to allopurinol alone in 280 adults with hematologic malignancies at risk of TLS. Both
rasburicase groups were superior to allopurinol alone in normalization of serum uric acid, but there were no differences in the incidence of clinical TLS or acute kidney injury [65]. The most common rasburicase-associated toxicities included rash and hypersensitivity. When rasburicase is used, it is important to recognize that the enzyme can continue to degrade uric acid in blood samples at room temperature. Samples must be collected in prechilled heparinized tubes, transported on ice, and analyzed within 4 hours of collection. Rasburicase is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency.

Outcomes with development of full-blown TLS are variable. In the reported cases of solid tumor TLS, the fatality rate was very high (36%) [66]. Institution of prophylaxis in patients identified as high risk (even those with solid tumors), which includes both rasburicase and consideration for early use of hemodialysis, is highly recommended [60]. Advances in oncologic emergencies, based on randomized, controlled trials or meta-analyses of such trials, are summarized in Table 95.6.

Therapeutic Apheresis:
Technical Considerations and Indications in Critical Care
LAURA S. CONNELLY-SMITH • THERESA A. NESTER

TECHNICAL RATIONALE AND INSTRUMENTS

Apheresis means to remove. Apheresis instruments are designed to separate whole blood into its component parts to selectively remove one component and return the remaining components to the patient. By processing one or more blood volumes, a significant amount of pathologic solutes or cells may be removed while the intravascular compartment remains relatively euvoletic. In an exchange procedure, replacement fluid or blood is given back to the patient to allow plasma or red cells to be removed. With any apheresis procedure, some type of anticoagulant is added to the circuit to ensure that blood flows freely.

Centrifugation apheresis instruments use either a continuous or a discontinuous flow method to deliver blood to the separation device where blood cells and plasma are differentially sedimented according to their specific gravity. Continuous flow methods draw blood into the extracorporeal circuit, separate blood into components in the centrifugation chamber, divert the unwanted component into a collection bag, and return nonpathologic components to the patient without interruption (Fig. 96.1). Dual venous/catheter access is required for these procedures. Discontinuous, or intermittent, flow methods accomplish the same steps but draw and process a discrete amount of blood into the
extracorporeal circuit and then return the processed effluent before another discrete volume of blood is removed. Discontinuous procedures take a longer time than continuous procedures but require only single vein/catheter access [1].

FIGURE 96.1 A: Basic circuitry and instrumentation of component removal in a therapeutic apheresis procedure. Anticoagulant is added to the patient’s blood as it is drawn and pumped to the separation device. The component to be collected is pumped from the device to a collection bag, and the remainder of the blood is returned, along with appropriate replacement fluid, to the patient. B: Circuitry and instrumentation for selective removal of pathogenic substance from the patient’s plasma. The patient’s anticoagulated blood is pumped to the separation device, and separated plasma is then delivered to the selective removal device. The purified plasma is then combined with the cellular portion of the patient’s blood and returned to the patient. AD, air detector; BP, blood pump; P, pressure monitor.

Some apheresis instruments, predominantly used in Asia and Europe, use a membrane filtration technique to isolate plasma. The extracorporeal membrane consists of either a flat plate or a hollow fiber with a pore size that excludes cellular components from the filtrate. The plasma that is separated in the instrument is diverted for disposal or treatment, whereas the other blood components are returned to the patient [2].

Specialized columns and instruments have been developed over the years to treat separated plasma, with the goal of selectively removing pathogenic proteins or other solutes [2,3]. One example is hypercholesterolemia therapy. Two different columns are approved for patients with familial hypercholesterolemia who have failed combination drug therapy. The heparin-induced extracorporeal low-density lipoprotein (LDL) precipitation (HELP) system and Liposorber LA-15 system target the removal of LDLs from separated plasma [3]. Additional columns and systems have been tested and used outside the United States. These include a dextran sulfate column to remove anti-DNA and anticardiolipin antibodies and immobilized polymyxin B or other adsorbers to remove inflammatory cytokines and mediators of sepsis [3]. One specialized methodology, called extracorporeal photopheresis (ECP), involves isolating peripheral white blood cells by leukapheresis, treating the cells with a psoralen drug, and exposing them to ultraviolet A light before returning the photoactivated cells to the patient [4]. A dedicated instrument approved by the Food and Drug Administration is used to perform ECP, which is beneficial for some patients with cutaneous T-cell lymphoma, graft-versus-host disease after hematopoietic stem cell transplantation, systemic sclerosis, and solid organ transplant allorejection [5]. Although ECP is usually an elective procedure, a critically ill patient may undergo treatment as part of a multimodality therapeutic approach.
The effectiveness of an apheresis procedure in reducing a plasma molecule or cellular component depends on two factors: (a) the distribution of that component between the intravascular and extravascular space and (b) the rate of regeneration of the component [6]. For solutes that move freely between intravascular and extravascular compartments, complete reequilibration between the compartments occurs at approximately 48 hours after a plasma exchange. Circulating blood cells also traffic between sites of vascular margination and/or splenic sequestration and this, in turn, can affect the efficiency of a therapeutic cytapheresis procedure.

The rate of intravascular regeneration of a pathologic solute or blood cell population after apheresis also depends on the rates of synthesis or production and decay or cell death. Plasma exchange typically removes large molecules at a rate that greatly exceeds their natural synthetic rate; thus, a simple one-compartment mathematical model is used to predict the depletion of soluble plasma substances. Assumptions of the model are that the plasma removed is replaced with a fluid devoid of the target substance, and that complete mixing of the replacement fluid with the remaining intravascular plasma volume occurs [6]. Figure 96.2 depicts the kinetics of removal and regeneration of plasma immunoglobulin G (IgG) and IgM after therapeutic plasma exchange (TPE). The reliability of the one-compartment model to predict removal of soluble substances may be limited by conditions that cause an expanded plasma volume, such as paraproteinemia, molecules with rapid synthetic rates, and situations where rebound IgG production occurs, such as in the setting of humoral solid organ rejection due to a preformed antibody [7].
FIGURE 96.2 Hypothetical depletion of whole body immunoglobulin (Ig) levels by therapeutic plasma exchange. The one-compartment model predicts that approximately 60% of the soluble substance will be removed from the plasma with a 1× plasma volume therapeutic exchange, and approximately 80% will be removed with a 1.5× volume exchange. Because roughly 50% of IgG distributes to the extravascular space, reequilibration between the intravascular and extravascular compartments occurs between sequential procedures, and 6 or 7 1× volume exchanges are needed to deplete whole body IgG to less than 10% of the pretreatment level. By comparison, IgM is predominantly intravascular, and, therefore, only 3 or 4 1× volume exchanges are needed to deplete whole body IgM to less than 10%. By increasing the processing to 1.5× plasma volumes, the same therapeutic goal would require three procedures to deplete IgM and five procedures to deplete IgG.

The efficiency of cell depletion by cytapheresis is less predictable than soluble substance removal by plasma exchange. Factors that may hinder the prediction include a rapid rate of cell production, such as occurs with untreated acute leukemia; the propensity of the spleen to sequester abnormal circulating cells or platelets; and miscalculation of the plasma volume of the patient. In general, a cytapheresis procedure in which 1.5 to 2.0 blood volumes are processed can be expected to remove
approximately 35% to 85% of the target cells [8].
ANTICOAGULATION AND FLUID REPLACEMENT

Citrate is the most commonly used anticoagulant for plasma exchange and cytapheresis procedures. Heparin is often used with ECP, specialized column extraction systems, and plasma membrane filtration. Current apheresis instruments limit both the anticoagulant (citrate or heparin) dose and rate of blood return based on the patient’s total blood volume. The operator can also adjust the ratio of anticoagulant to whole blood being processed [9].

The acid-citrate-dextrose (ACD) solution effectively chelates free or ionized plasma calcium, thereby preventing coagulation of blood and plasma in the apheresis circuit. The precise decrease in ionized calcium in vivo during an apheresis procedure is difficult to predict, as this depends on dilution, metabolism, redistribution, and excretion of infused citrate [9]. Fluid replacement with plasma or albumin may decrease the ionized calcium further because of citrate in the plasma or calcium binding by albumin. Ionized calcium may typically decrease by 25% to 35%, as measured during donor apheresis procedures [9].

Citrate does not produce an anticoagulant effect in vivo. The half-life in patients with normal renal and hepatic function is approximately 30 minutes. In a patient with severe liver disease, where citrate will not be as quickly metabolized, the operator should reduce the amount and/or rate of ACD used during an exchange. In critically ill patients needing plasma exchange, it is advised that ionized calcium be monitored and intravenous calcium replacement be provided as needed. Some apheresis services use protocols for the infusion of intravenous calcium gluconate or calcium chloride during all TPEs [10].

Continuous reinfusion of extracorporeal heparin during an apheresis procedure will affect the patient’s hemostatic parameters. The effect is measurable until the drug is metabolized, usually within 60 to 120 minutes of finishing the procedure. For patients already therapeutically anticoagulated with heparin, the anticoagulation normally used with apheresis may be reduced or eliminated. The primary providers of critically ill patients must communicate with the apheresis team all information regarding systemic anticoagulation, coagulopathy, and contraindications to anticoagulation, especially when heparin is planned for a therapeutic procedure. It is particularly important to document if the patient has known or suspected heparin-induced thrombocytopenia.
Replacement fluid used in plasma exchange may consist of plasma, albumin, or saline. The type of fluid depends on (a) the patient’s baseline hemostatic parameters, particularly fibrinogen; (b) the anticipated number and frequency of procedures; and (c) the condition being treated. For a patient with a neurologic illness, such as acute Guillain–Barré syndrome, 1 to 1.5 plasma volume exchanges are typically performed every other day with 5% albumin as replacement fluid. This regimen and schedule allows the fibrinogen level to recover between procedures. Alternatively, if a condition requires that plasma exchange be performed daily, some plasma replacement will likely be needed to maintain the patient’s fibrinogen at a hemostatic level. For conditions where a plasma component is felt to be an important part of the therapy, such as with thrombotic thrombocytopenic purpura, plasma should comprise at least half of the replacement fluid [11]. In such cases, fibrinogen and other coagulation factors will not be depleted.

An apheresis instrument that uses a centrifugation technique must deliver a specific volume of packed red cells to the separation chamber to maintain the cell/plasma density gradient necessary for efficient selective extraction. The extracorporeal blood volume (ECV) necessary for this purpose varies according to the specifications of the instrument and disposable tubing kit and the hematocrit of the patient. The AABB (formerly American Association of Blood Banks) recommends that the ECV for a general procedure should not exceed 15% of a patient’s total blood volume [12]. The implications for a therapeutic apheresis procedure can be illustrated by the following example. A 60-kg adult with a hematocrit of 40% has a total blood volume of: 60 kg × 70 mL per kg (the standard conversion factor for an adult male) = 4,200 mL; and a red cell volume of 4,200 mL × 40/100 = 1,680 mL. If the instrument requires 200 mL of extracorporeal red cell volume, then the ECV required to deliver that 200 mL will be 200/1,680 = 0.12, or 12% of the total blood volume. If, however, the same patient has a hematocrit of 20%, the red cell volume will be 4,200 mL × 20/100 = 840 mL; and the required ECV will be 200/840 = 0.24 or 24% of the total blood volume, which exceeds the AABB safety limit. Allogeneic red cells are required when the ECV exceeds 15%. These are either given to the patient as a transfusion prior to the procedure (to increase their pretreatment red cell volume), or used to “prime” the apheresis circuit at the beginning of the procedure (and returned to the patient as part of the return fluid).
VASCULAR ACCESS

The type of vascular access required for therapeutic apheresis depends on the status of the patient’s peripheral veins, the condition being treated, and the anticipated frequency and duration of treatment. The vein or catheter must be able to withstand negative pressures associated with inlet rates ranging from 50 to 150 mL per minute for the draw line and up to 150 mL per minute for blood being returned to the patient. For a patient needing only one exchange, it may be possible to use antecubital or forearm veins. A 16- to 18-gauge Teflon or silicone-coated steel, back-eye apheresis, or dialysis-type needle is required for the draw line. The patient ideally will be able to help by squeezing a ball during the exchange.

A large bore central venous catheter is often required for critically ill patients, especially those requiring daily procedures. Temporary or long-term tunneled catheters for adults weighing more than 40 kg should be at least 10-Fr size (Table 96.1). Smaller diameter short-term catheters are acceptable for smaller adults and pediatric patients. Plastic central venous catheters such as those used for cardiac pressure monitoring are not adequate for the draw line because they collapse under the negative pressure generated from the high inlet flow rate. These catheters or a peripheral vein may be useful as return access under certain circumstances.

Peripherally inserted central venous catheter lines and standard port-a-catheters are also not suitable options to accommodate the negative pressures and blood flow rates required. Subcutaneous ports with a reservoir-type chamber can accommodate flow rates required for some apheresis procedures, typically, chronic red blood cell exchanges rather than plasma exchanges [15]. Arteriovenous fistulas created for dialysis access can be used for therapeutic apheresis [13]. The critical care team should consult with the apheresis team prior to placing venous access for the procedure.
LIMITATIONS AND POTENTIAL ADVERSE EVENTS

When considering therapeutic apheresis, certain limitations should be remembered. First, apheresis is not the same as dialysis. It is not usually possible to end a procedure with a large net negative fluid balance (i.e., >200 to 400 mL) because the deficit is colloid rather than crystalloid, and hypotension is likely to occur. A safe end fluid balance is plus or minus 10% to 15% of the total blood volume. In addition, it is not recommended that red cells be transfused during the apheresis procedure (other than at the start as a blood “prime”) because the cell separation gradient and cell/plasma interface in the separation chamber may be disturbed. Second, the procedure is almost always an adjunctive, rather than definitive therapy for the condition being treated. Thus, although apheresis can be performed in very ill patients, one must carefully consider the risks that are associated with hemodynamic instability, hematologic abnormalities, the need for vascular access, and the priorities for more urgent primary treatments.

Possible adverse complications related to therapeutic apheresis are shown in Table 96.2. Central line complications include procedure-related events, infection, and bleeding (Chapter 6). Citrate toxicity occurs in 1.5% to 9.0% of therapeutic procedures [16]. Higher risk is associated with larger process volumes, longer procedure duration, nonphysiologic bleeding, severe anemia, unstable vital signs, liver failure, alkalosis due to hyperventilation, and use of replacement fluid consisting of blood components that contain citrate as the anticoagulant [16,17]. Signs and symptoms of hypocalcemia can include a metallic taste in the mouth, muscle or gastrointestinal cramps, perioral numbness, distal paresthesias, and chest tightness. In sedated or unconscious patients, severe citrate toxicity may manifest as tetany, muscle spasm including laryngospasm, a prolonged QTc interval, and decreased myocardial contractility [16]. Hypomagnesemia and hypokalemia may also occur, as the kidneys increase cation excretion into the urine to facilitate excretion of the citrate load. Although rare, fatal arrhythmias have occurred during therapeutic apheresis. To avoid these complications, ionized calcium should be monitored and intravenous calcium infused, as indicated, either through the return line or as an additive with the albumin replacement fluid. Some apheresis practitioners will add small amounts of potassium to albumin to minimize the risk of hypokalemia; otherwise, one should consider monitoring of serum potassium for intensive regimens that use albumin as the replacement fluid [17].
Hypotension or vasovagal reactions have a reported incidence of 1.7% [17]. Patients with preexisting hemodynamic instability or diminished vascular tone, as seen in certain neurologic disorders, may be at particular risk. In such patients, a net negative end fluid balance must be avoided. Transfusion reactions may occur if blood components are part of the replacement fluid. Allergic reactions have also been reported in some patients receiving albumin as the replacement fluid.

Hemostatic alterations and bleeding may occur in severely ill patients with baseline coagulopathy and/or severe thrombocytopenia. A typical 1.3-volume plasma exchange using albumin depletes most coagulation factors to approximately 25% to 45% of their preprocedure values [18]. Repletion time of these coagulation factors depends on their respective rates of synthesis, with most factors returning to baseline values by 24 hours. The exception is fibrinogen, which takes about 3 days to return to baseline values. Because fibrinogen levels are the most severely affected during the course of a series of plasma exchanges, preprocedure fibrinogen levels should be monitored, especially if the replacement fluid does not include at least 50% plasma. Therapeutic leukapheresis removes a portion of circulating platelets, and this decrement could be clinically significant in a patient with preprocedure severe thrombocytopenia. The postprocedure platelet count and coagulation status should be monitored in a critically ill patient, particularly if an invasive procedure is needed shortly after apheresis.
In some patients undergoing plasma exchange with albumin as the replacement fluid, a severe reaction consisting of flushing, hypotension, bradycardia, and dyspnea has been linked to concomitant use of angiotensin-converting enzyme (ACE) inhibitors [19]. This reaction is mediated by bradykinin, which is thought to be generated by prekallikrein-activating factor in the albumin preparation. These reports have led to the recommendation that ACE inhibitors be withheld for 24 to 48 hours (depending on the half-life of the specific drug) before plasma exchange using albumin [19]. If an emergency exchange is required in a patient on an ACE inhibitor, fresh frozen plasma (FFP) should be used as the replacement fluid to avoid this reaction. Similar reactions involving ACE inhibitors have been seen in patients undergoing plasma treatment with specialized columns; thus, similar precautions must be followed [20].

An additional potential adverse effect of repeated plasma exchange is the removal of highly protein-bound therapeutic drugs and plasma immunoglobulins. The exact effects of exchange on individual drug levels have not been delineated. To avoid this complication, medications should be administered following a plasma exchange procedure whenever possible. Immunoglobulin levels should also be measured periodically in immunosuppressed patients undergoing a series of plasma exchanges, as these proteins will be nonselectively depleted from the circulation, and severe hypogammaglobulinemia could further predispose the patient to infections [17].
Evidence-based guidelines for clinical applications are published by the American Society for Apheresis (ASFA) every few years [21]. Medical conditions are placed into categories from I to IV, with I indicating that therapeutic apheresis is known to be an effective primary or adjunct therapy based on randomized controlled clinical trials or broad noncontroversial experience, and category IV indicating no demonstrated efficacy, and possibly even a negative impact of therapeutic apheresis for the condition [5]. Examples of evidence-based indications for therapeutic apheresis are shown in Table 96.3.

Category I: Disorders for which apheresis is accepted as first-line therapy, either as a primary standalone treatment or in conjunction with other modes of treatment. Category II: Disorders for which apheresis is accepted as second-line therapy, either as a standalone treatment or in conjunction with other modes of treatment. Category III: Disorders for which the optimum role of apheresis therapy is not established. Decision-making should be individualized. Category IV: Disorders in which published evidence demonstrates or suggests apheresis to be ineffective or harmful. Institutional review board approval is desirable if apheresis treatment is undertaken in these circumstances.

Note: The grade system has also been assigned in an effort to parallel an approach more commonly used to evaluate therapeutic recommendations.

ANCA, antineutrophil cytoplasmic antibody; IgA, immunoglobulin A; IgG, immunoglobulin G; IgM, immunoglobulin M.

**Therapeutic Plasma Exchange**

In the intensive care unit, TPE is likely to be the most frequent apheresis procedure used. Antibody-mediated conditions known to respond to plasma exchange include thrombotic thrombocytopenic purpura [11,22,23]; demyelinating diseases including acute inflammatory demyelinating polyneuropathy/Guillain–Barré syndrome [24–27]; severe, acute idiopathic inflammatory demyelinating diseases [24,28]; myasthenic crisis [24,29–32]; demyelinating polyneuropathy with IgG and IgA [24]; antiglomerular basement membrane (anti-GBM) (Goodpasture’s) disease; and pulmonary hemorrhage associated with other forms of rapidly progressive glomerulonephritis (RPGN) [33,34,35].

Randomized trials and systematic reviews have directed decision-making in the use of therapeutic apheresis as a treatment modality (Table 96.4); however, in certain conditions, there limited data are available with its effectiveness and optimal role yet to be determined.

The table above summarizes various studies involving the use of plasma exchange (PE) in different conditions, including multiple sclerosis, rapidly progressive glomerulonephritis (RPGN), renal vasculitis, and myasthenia gravis. The key findings indicate the effectiveness of PE in reducing disease progression and improving outcomes in these conditions.
Myasthenia gravis [32] | 84 | PE vs. intravenous immunoglobulin (IVIg) | Day 14 variation of quantitative myasthenia gravis score

| immunoglobulin (IVIg) | myasthenic muscular score | +18 PE (n = 41) | +15.5 IVIg (n = 46; p = 0.65) |

| PE | −3.2 IVIg (n = 41) | −4.7 PE (n = 43; p = 0.13) |

CI, confidence interval; n, number; NS, not significant; RR, relative risk.

With the muscle-specific receptor tyrosine kinase antibody (MuSK-Ab) form of myasthenia gravis, TPE appears to be a more effective therapy than intravenous immunoglobulin (IVIg) infusion [29,36]. By comparison, with the acetyl cholinesterase receptor (AChR-Ab) form of myasthenia gravis, and with Guillain–Barré syndrome, plasma exchange is effective but not superior to or as tolerable as IVIg infusion [26,27,31] (see Table 96.4). For patients with acute attacks of demyelination, plasma exchange may be useful. Although there is only one randomized controlled trial [28], observations from this study and retrospective data indicate that at least 50% of patients with neuromyelitis optica (NMO), characterized by spinal and visual involvement, achieve increased function with plasma exchange, and that patients with steroid-refractory optic neuritis may also achieve some benefit [37]. A potential mechanism of action of TPE with NMO is modulation of the serum autoantibody NMO-IgG, which has been implicated in disease pathophysiology [38].

The optimum role of TPE in the setting of severe sepsis and multiorgan dysfunction is not established. Two randomized controlled trials in adults using either continuous plasma filtration versus supportive care [39] or plasma exchange versus standard care [40] have been published. No differences were observed in the 14-day mortality rates of 14 patients with sepsis syndrome receiving 34 hours of continuous plasma filtration and 16 untreated control patients (57% vs. 50%) [39] (see Table 96.4). By comparison, the 28-day mortality rate was 33.3% among 54 patients with sepsis and septic shock treated with one or two TPE treatments compared with 53.8% among 52 nontreated control patients (p = 0.05) [40] (see Table 96.4). When differences between the control and experimental
groups were considered using multiple logistic regression, the significance of the treatment variable on mortality was $p = 0.07$. A recent meta-analysis of these two trials demonstrated insufficient evidence to recommend plasma exchange as an adjunctive therapy for patients with sepsis or septic shock [41].

A nonrandomized observational cohort study evaluated hemodynamic and mortality outcomes in critically ill surgical patients with sepsis treated with TPE and continuous venovenous hemofiltration [42]. No overall difference in mortality was observed between treated patients and an untreated historical control group (42% vs. 46%); however, patients with organ failure limited to one or two systems appeared to benefit, with mortality rates of 10% among 10 treated patients versus 38% among 16 untreated control patients [42]. Although encouraging, these data must be supported by results from additional well-designed randomized controlled trials before plasma exchange can be recommended as a noninvestigational therapy for this indication [41,43].

A meta-analysis of the available limited data on plasma exchange for patients with renal vasculitis and RPGN suggests that TPE may reduce the composite end point for end-stage renal failure or death [44]. The evidence supporting a potential benefit of plasma exchange derives from retrospective and case–control studies among more severely affected patients [45,46], whereas randomized controlled trials have yielded supportive results in some studies [47] but not others [48,49] (see Table 96.4). For patients with renal vasculitis due to causes other than anti-GBM disease, a review of randomized controlled clinical trials demonstrated a significant reduction in end-stage renal disease with use of TPE [50].

**Red Blood Cell Exchange**

Use of red blood cell exchange may be warranted for selected patients with sickle cell disease who are experiencing stroke, acute chest syndrome (ACS), priapism, splenic/hepatic sequestration, or multiple organ failure as a complication of their disease [51]. Because automated red cell exchange (also called erythrocytapheresis) can more rapidly reduce the level of hemoglobin S-positive cells (to the goal of <30%) [5]. Although maintaining euvoolemia and minimizing hyperviscosity complications, this modality has been utilized in preference to simple transfusion by many centers. Although this makes intuitive sense, the data needed to show a clear advantage of automated red cell exchange over simple transfusion are lacking. An observational, retrospective cohort analysis found no differences in postprocedure and total lengths of stay for patients with ACS treated with automated red cell exchange ($n = 20$) compared with those who received simple transfusion support ($n = \ldots$)
Moreover, the apheresis group required, on average, four times as many units of donor red cells.

Manual exchange transfusion, in which phlebotomized blood is replaced by simple transfusions of allogeneic red cells and FFP, has the added theoretical advantage of reducing the levels of plasma inflammatory mediators, which might augment vasooclusive tissue injury in patients with ACS [53]. One nonrandomized trial used a combination of TPE and automated red cell exchange for seven patients with severe ACS and multiorgan failure, and observed an 86% 1-year survival [54]. Despite these observations, the optimal approach for critically ill patients with ACS and other severe complications remains undefined, in part because crossmatch-compatible blood may be very difficult to locate for heavily transfused sickle cell patients with multiple alloantibodies. Adequately powered randomized clinical trials are sorely needed to clarify the indications for automated or manual red cell exchange versus simple transfusion support and the potential role of TPE [51].

Red cell exchange may also be useful in patients with severe clinical manifestations of falciparum malaria or babesiosis [55]. Although a meta-analysis performed in 2002 showed no survival benefit of red cell exchange compared with antimalarials and aggressive supportive care alone [56], many case reports and series suggest a benefit in clinical status with rapid reduction of hyperparasitemia using adjunctive manual or automated red cell exchange [57–59]. In 2013, however, the Centers for Disease Control and Prevention (CDC) revised their previous recommendation on the use of red cell exchange as adjunctive therapy for the treatment of severe malaria [60]. They now no longer recommend its use based on a review of the published literature that found no evidence of overall survival benefit for exchange transfusion as adjunctive therapy [61]. ASFA currently continues to support certain indications for the use of exchange transfusion in severe malaria [62] but recognizes that quinidine (or artesunate) administration should not be delayed and may be given concurrently with the exchange. As in fulminant malaria, several case reports demonstrate that patients with overwhelming parasitemia from Babesia also quickly respond to red cell exchange [63].

Automated red cell exchange may be considered as an alternative to large volume phlebotomy in selected patients with uncontrolled erythrocytosis and polycythemia vera with acute thromboembolism, severe microvascular complications, or bleeding [64]. This method can quickly and more safely normalize the hematocrit in patients who are
hemodynamically unstable.

**Leukapheresis**

Leukapheresis (i.e., selective removal of white blood cells) is commonly used in patients with acute myeloid leukemia (AML) and hyperleukocytosis experiencing symptoms of leukostasis. Signs and symptoms typically manifest as neurologic alterations (confusion, mental status changes, altered level of consciousness) or pulmonary compromise (hypoxemia, diffuse lung infiltrates). Leukapheresis is indicated in patients with AML and a circulating blast count greater than 50,000 per μL who are clearly demonstrating signs of intravascular leukostasis (i.e., symptoms not attributable to infection, bleeding, or metabolic derangements) [65,66]. Leukapheresis may be warranted sooner in monocytic subtypes of AML, as signs of intravascular leukostasis may be seen at blast counts less than 50,000 per μL [66] after the start of chemotherapy. Because of the high mortality rate associated with leukostasis, leukapheresis is often considered an urgent, lifesaving procedure and is recognized as a Category II indication according to ASFA [5]. Metaanalysis on the use of leukapheresis in hyperleukocytosis (retrospective data) has however found no impact on the early death rate in AML [67]. The potential benefits of urgent leukapheresis should be discussed with the apheresis physician; however, definitive treatment with chemotherapy should not be delayed by the leukapheresis procedure and is required to prevent the rapid reaccumulation of blasts. Prophylactic leukapheresis could be considered in AML patients with circulating blast counts greater than 100,000 per μL, particularly if the count is rapidly rising but definitive therapy with induction chemotherapy should not be delayed [5]. In comparison with AML, leukostasis complications are rare in patients with acute lymphoblastic leukemia (ALL) and circulating blast counts less than 400,000 per μL. Studies have shown that prophylactic leukapheresis for asymptomatic patients with ALL and hyperleukocytosis does not offer additional benefit above aggressive supportive care and chemotherapy [68].

**Plateletpheresis**

Plateletpheresis should be considered as an urgent intervention in patients experiencing thrombosis or hemorrhage in the setting of uncontrolled thrombocytosis associated with a stem cell disorder [69]. Such stem cell disorders include essential thrombocythemia, polycythemia vera, idiopathic myelofibrosis, chronic myeloid leukemia, or unclassified myeloproliferative neoplasm. The goal of plateletpheresis is to decrease the platelet count (ideally below 600,000 per μL) and to maintain the count until pharmacologic cytoreductive therapy takes effect.
[5]. Plateletpheresis may also be electively considered for the prevention of perioperative thrombohemorrhagic complications in patients with myeloproliferative neoplasms undergoing splenectomy [70].
APHERESIS CONSULTATION

For any apheresis procedure, consultation with the apheresis team can be useful in assessing experience and available data for a given condition. The apheresis physician and team should be viewed as partners in determining the treatment plan. Initial discussion with the apheresis physician will include whether the indication is urgent or routine, the impact of apheresis on other treatment modalities, volume management, fluid replacement, and vascular access. Ongoing discussions should continue through the patient’s course so that appropriate adjustments can be made to optimize the therapy.

PHARMACOLOGY,
OVERDOSES, AND
POISONINGS
STEVEN B. BIRD • LUKE YIP • KENNON
HEARD
The objective of this chapter is to provide the general intensivist with both an overview and an approach to the management of the critically ill poisoned patient. General concepts germane to the intensive care unit (ICU) will be introduced and explored. Every attempt has been made to be as evidence based as possible, within the intrinsic limitations of the medical toxicology literature.

Because overdose studies cannot ethically be performed in humans and animal data may not be available or applicable to humans, predicting the severity of poisoning must be based on toxicodynamic data from previously published reports of human poisonings. However, such data are often incomplete or altogether unavailable and are always limited by the accuracy of the overdose history.

Poisoning or intoxication is defined as the occurrence of harmful effects resulting from exposure to a foreign chemical or xenobiotic. Such effects may be local (i.e., limited to exposed body surfaces), subjective (i.e., symptoms only) or systemic and objective (e.g., behavioral, biochemical, cognitive, or physiological). In the absence of signs or symptoms, external or internal body contact with a potentially harmful amount of a chemical is merely an exposure. An overdose is an excessive exposure to a chemical that in specified (e.g., therapeutic) amounts is normally intended for human use. Whether an exposure or overdose results in poisoning depends more on the conditions of exposure (primarily the dose) than the identity of the agent involved. Ordinarily safe chemicals, even those essential for life such as oxygen and water, in excessive amounts or by an inappropriate route can result in harmful effects. Conversely, by limiting the dose, chemicals usually thought of as poisons can be rendered harmless. Poisoning is distinguished from
adverse allergic, intolerance, and idiosyncratic pharmacogenetic reactions in that effects are concentration or dose related and, hence, predictable. As such, it includes adverse drug reactions due to unwanted secondary effects and pharmacokinetic and pharmacodynamic interactions.

Poisonings, exposures, and overdoses may be characterized by the route, duration, and intent of exposure. Ingestion, dermal or ophthalmic contact, inhalation, and parenteral injection (including bites and stings) are the most common routes, but rectal, urethral, vaginal, bladder, peritoneal, intraocular, and intrathecal exposures can also occur. Events that occur once or during a short period of time are considered acute, whereas those that occur repeatedly or over a prolonged time interval are said to be chronic.

**EPIDEMIOLOGY**

Although the true incidence of poisoning is difficult to accurately quantify, it is clearly a significant medical problem. Just over 2 million human exposures were reported to the National Poison Data System in 2013 [1]. Of these, 20% to 25% are treated at a health care facility, and approximately 6% are admitted to a hospital. Half of those admitted are treated in an ICU. In other countries, the ICU admission rate for those evaluated at a health care facility varies from 5% to 22% [2].

Exposures and poisonings are responsible for 1% to 5% of emergency department visits, 5% to 10% of all ambulance transports, 5% to 14% of adult ICU admissions, and 2% to 5% of pediatric hospital admissions [2–4]. In addition, 25% of routine medical admissions involve some form of drug-related adverse patient event (an adverse drug reaction or noncompliance), and up to 30% of acute psychiatric admissions are prompted by attempted self-harm via chemical exposure. Although the incidence of poisoning in children has decreased since the introduction of the Poison Prevention Packaging Act in 1970 [5], the overall incidence of poisoning increased over the past decade, particularly that due to suicide attempts in teens, middle-aged adults, and the elderly. The volume of calls handled by United States Poison Centers has flattened out over the past year [2]. Poisonings with less serious outcomes have decreased by 3.7% per year since 2008, while the incidence of more serious outcomes and death has increased by 4.7% per year since 2000 [2]. Poisoning is second only to firearms as the leading cause of suicide [2]. Poisoning is the second leading cause of injury death [1]. The yearly medical cost for the treatment of poisoning in the United States is estimated to be 26 billion [6]. Poisoning accounts for 6% of the economic costs of all injuries in the United States [6].
Most exposures reported to US poison centers are acute (90.9%), unintentional (83.2%), occur at home (92.9%), cause minor or no harmful effects (95%), result from ingestion (78.4%), and involve children 6 years of age or younger (51.2%) [1].

Poisoning accounts for 2% to 14% of all ICU admissions, with an average length of stay of about 3 days [2,4]. The mortality rate for such patients varies from 0.6% to 6.1% [3,4]. Although only 1,218 poisoning fatalities were reported by US poison centers in 2013 [1], death certificate data indicate that the true number of poisoning deaths is 20 to 50 times higher [7]. Poison center statistics vastly underestimate mortality from poisoning because they rarely capture cases in which the victim is found dead and goes directly to the medical examiner.
PHARMACOLOGICAL CONCEPTS

Toxic exposures all undergo the same pharmacological steps, as outlined in Table 97.1. Clinician familiarity with toxicokinetics is essential for predicting the effect of a particular exposure and guiding appropriate treatment and disposition. Only a brief overview of these concepts is presented here. The reader is referred to other sources for additional information [8–10]. Details regarding the disposition and toxic effects of specific agents can be found in subsequent chapters and other references [9–16].

</table>

**Mechanism of Action**

Most chemicals are absorbed and cause systemic poisoning by selectively binding to and disrupting the function of specific targets (e.g., enzymes, proteins, membrane lipids, or neurohumoral receptors). Effects may be systemic or limited to a specific organ or tissue, depending on the distribution and location of target site. Poisoning is usually functional and reversible. Hence, if end-organ function can be supported, complete patient recovery is possible upon toxin elimination. However, if normal activity of the target site is essential for cell viability, a toxic exposure may result in necrosis. Agents that can cause fatal cellular damage include acetaminophen, carbon monoxide, corrosives, toxic alcohols, heavy metals, and neurotoxic hydrocarbons.

**Absorption**

Absorption involves the translocation of chemicals across the membranes of cells that make up mucosal surfaces, pulmonary epithelium, and skin,
all of which function as biological barriers. Translocation occurs by filtration or passive diffusion through gaps or membrane pores by dissolving in and diffusing through the membrane itself (e.g., lipid-soluble chemicals), or by attaching to carrier molecules in the membrane, which actively or passively facilitate diffusion (e.g., water-soluble chemicals). The rate and extent of absorption depends on physical properties of the chemical and the route of exposure. In general, only chemicals that are small (i.e., <4 nm in diameter), have low molecular weight (i.e., <50 Da), and are soluble in both water and lipids at the pH of body fluids can readily cross membranes.

Absorption after intravenous injection is complete and almost instantaneous. Peak arterial and venous blood concentrations occur within 30 to 90 seconds. Most toxins cross biological membranes by simple passive diffusion. The rate at which this occurs is governed by Fick’s law of diffusion.

\[
\text{Rate of Diffusion} = \frac{dQ}{dt} = \frac{DAK(C_1 - C_2)}{d}
\]

where \( D \) is the diffusion constant (constant for each toxin), \( A \) is the membrane surface area, \( K \) is the partition coefficient (represents the lipid: water partitioning of the toxin), \( d \) is the membrane thickness, and \( C \) is the toxin concentration. Pulmonary absorption is rapid but incomplete. Blood concentrations peak within seconds to minutes. The absorption of chemicals after intramuscular or subcutaneous injection is slower but relatively complete. Peak blood levels generally occur within an hour of administration. Poor water solubility (low \( K \)) is responsible for the slow absorption and long duration of action of intramuscular depot formulations (e.g., neuroleptics).

The rate and extent of absorption after ingestion are variable. Peak blood levels are typically noted within 0.5 to 2.0 hours of a therapeutic dose. The absorbed dose is proportional to, but not necessarily equal to, the administered dose. The rate and extent of absorption after contact with other mucosal surfaces (e.g., oral, nasal, ophthalmic, and rectal) is similar to ingestion. Skin absorption, if it occurs at all, is usually considerably slower. Regardless of route, absorption tends to follow first-order kinetics (i.e., the amount of chemical absorbed per unit of time is directly proportional to its concentration). Hence, threshold tissue concentrations are usually reached more quickly and effects begin sooner after an overdose than after a therapeutic dose.

Zero-Order Kinetics: rate of reaction is not proportional to toxin concentration

First-Order Kinetics: rate of reaction is proportional to toxin
concentration

The dissolution and solvation of particulate material is often a rate-limiting step in gastrointestinal (GI) drug absorption. Hence, pill, solid, and suppository formulations tend to be absorbed more slowly than liquids, powders, or suspensions. Slow dissolution and solvation also account for the delayed and prolonged absorption of enteric-coated tablets (e.g., aspirin, potassium), sustained-release preparations (e.g., cardiovascular drugs, lithium, phenytoin, and theophylline), drugs that tend to form concretions (e.g., ethchlorvynol, glutethimide, heavy metals, iron, lithium, and meprobamate), and those with poor water solubility (e.g., carbamazepine and digoxin). The rate of dissolution is also inversely related to the tablet concentration. Hence, absorption generally takes longer and peak effects occur later after an overdose than after a therapeutic one.

Ingested chemicals are predominantly absorbed from the small intestine rather than the stomach, because the small intestine has a larger surface area. Hence, decreased gastric emptying or bowel activity caused by the presence of food, disease, or the effects of ingested agents (e.g., anticholinergics, opioids, sedative-hypnotics, and salicylates) can also delay or prolong absorption. Food and coingestants may decrease absorption by binding to the chemical within the gut lumen or by competitively inhibiting its dissolution and translocation. Absorption may also be decreased if intestinal motility is excessive.

Distribution

During distribution, chemicals may become bound to and inactivated by endogenous nontarget molecules such as serum proteins. The final distribution of chemical is uneven and reflects its affinity for active and inactive binding sites and the locations of such sites. It is also influenced by biological variables such as age, sex, weight, and disease states as they relate to body composition (e.g., water, fat, and muscle content) and serum protein concentrations. The extent of distribution of a chemical is reflected by its apparent volume of distribution, measured in liters per kilogram of body weight, and calculated most simply by dividing the amount of chemical in the body (i.e., the absorbed or bioavailable dose) by its plasma concentration.

\[
\text{Volume of Distribution} = \frac{\text{Bioavailable Dose}}{\text{Plasma Concentration}}
\]

Because distribution is also a translocation process, it is influenced by the same chemical characteristics as absorption and follows first-order kinetics. Distribution generally occurs much faster than absorption, as evidenced by the occurrence of peak effects within minutes of an IV drug
injection. Slow distribution is partly responsible for the delayed onset of action of some agents (e.g., digitalis, heavy metals, lithium, and salicylates).

**Tissue Concentration**

The severity of poisoning reflects the concentration of a chemical at its site(s) of action and is proportional to the dose. Because the blood concentration of a chemical is also proportional to the dose, blood levels are sometimes used as a surrogate to assess the severity of poisoning. However, blood and target site concentrations are not always in steady-state equilibrium. When distribution occurs more slowly than absorption (e.g., after IV administration, inhalational exposure, and the ingestion of agents with inherently slow distribution), blood levels may be higher than those in tissue. Conversely, when redistribution of a chemical from tissue to blood occurs more slowly than elimination (e.g., after extracorporeal removal), blood levels may be lower than those in tissue. In both instances, blood levels do not accurately reflect those in tissue and do not correlate with the severity of poisoning.

Age, genetic influences, tolerance, underlying disease, and the presence or absence of other chemicals may have synergistic or antagonistic effects and may also influence the response to a given level of toxin exposure. The effect of metabolites must also be considered. Many chemicals have metabolites that remain pharmacologically active. Some (e.g., acetaminophen, toxic alcohols, chlorinated hydrocarbons, meperidine, paraquat, and certain organophosphate insecticides) undergo metabolic activation, resulting in the production of compounds that are more toxic than the parent one.

**Metabolism/Elimination**

Elimination of chemicals from the body (detoxification) is accomplished by urinary, pulmonary, GI, and glandular (e.g., bile, milk, tears, saliva, and sweat) excretion or metabolic inactivation. Hepatic metabolism and renal excretion are the major routes of elimination for most agents. Pulmonary excretion also plays a major role in the elimination of gases and volatile chemicals. Elimination generally follows first-order kinetics. For some toxins, hepatic metabolism has a finite capacity (i.e., becomes “saturated”) and proceeds at a constant rate (zero-order kinetics). When the primary route of elimination is a zero-order metabolism, a small
increase in dose can result in a large increase in blood and tissue concentrations and potential poisoning. Chemicals exhibiting such metabolism include alcohols, phenytoin, salicylate, and theophylline.

Renal excretion is accomplished by translocation processes (e.g., glomerular filtration, tubular secretion, and reabsorption) and is therefore influenced by the same factors as absorption and distribution. Any condition that impairs hepatic or renal blood flow or function can decrease toxin elimination. Metabolic enzymes are also subject to genetic influences and to induction or inhibition resulting from past or current chemical exposures. Regardless of the kinetics and route of elimination, the time required for elimination increases as the tissue concentration of chemical increases. Hence, the duration of the effect tends to be longer after an overdose than after a therapeutic dose.
CLINICAL CONSIDERATIONS

The principal objectives in the diagnosis and evaluation of the poisoning are recognition of an exposure or poisoning, identification of the offending agent(s), prediction of potential toxicity, and assessment of the severity of clinical effects. Treatment objectives include resuscitation, prevention of further absorption, enhancement of elimination, and the administration of antidotal or novel therapy (Table 97.2).

<table>
<thead>
<tr>
<th>TABLE 97.2 Treatment Objectives—General Principles</th>
</tr>
</thead>

</tr>
</tbody>
</table>

Early accurate diagnosis is a prerequisite for optimal management. The priority of assessment and treatment objectives depends on the phase of poisoning [17]. During the preclinical phase (the time between exposure and the onset of clinical or laboratory evidence of toxicity), management priorities include chemical identification, prediction of toxicity, and prevention of absorption (decontamination). The sooner decontamination is accomplished, the greater its efficacy. Hence, the physical examination and gathering of ancillary data should initially be brief. Assessment should focus on the exposure history, whether or not poisoning is likely to ensue, and whether or not decontamination is indicated.

During the toxic phase (the time between the onset of toxicity and its peak), assessment of the severity of poisoning, resuscitation, prevention of further absorption, enhancement of elimination, and antidotal/novel therapy are the primary objectives. If the patient is critically ill, the history, physical examination, and diagnostic testing must be conducted concurrently with resuscitation.

During the resolution phase (the time between peak toxicity and full recovery), continued supportive care, enhancement of elimination, antidotal therapy, and reassessment of severity (evaluation of the response to treatment) are the most important management considerations. Measures to prevent subsequent reexposure should also be initiated before discharge.
Recognition of Poisoning

Although poisoning can cause a wide variety of nonspecific signs and symptoms, the diagnosis can usually be established by the history, physical examination, routine and toxicologic laboratory evaluation, and the clinical course. Ideally, criteria similar to Koch’s postulates for infectious disease should be met: A chemical is identified in or on the body in an amount known to cause the observed signs and symptoms within the reported time frame. In reality, the diagnosis is often made on the basis of a history of exposure, a clinical course consistent with poisoning, and exclusion of other etiologies.

Making the diagnosis can be easy when an accurate history of exposure is available. However, patients may be unaware of an exposure, unwilling to admit to one, or unable to give a history at all. Patients may give a history that is vague, confusing, or intentionally disguised.

Circumstances that should arouse suspicion of occult poisoning include sudden or unexplained illness in a previously healthy individual; similar unexplained symptoms in a group of individuals; a psychiatric history, alcoholism, or drug abuse; a recent change in health, economic status, or social relationships; and the onset of illness shortly after ingesting food, drink, or medication. Poisoning should always be considered in patients with metabolic abnormalities (especially acid–base disturbances), gastroenteritis, or changes in behavior or mental status of unclear etiology. Leakage of illicit drug packets that have been ingested or concealed in body cavities should be suspected in patients with altered mental status or unusual behavior who have just arrived from abroad (especially Asia and South America) or who have recently been arrested or incarcerated for criminal activity [18,19]. Drug intoxication is a risk factor for trauma and suicide and should also be considered in all injured patients.

To avoid missing the diagnosis of poisoning, the physician must specifically inquire about toxin exposure. In suspicious cases, the physician should assume the role of detective to elicit historical support for the diagnosis. Paramedics, police, and family, friends, employer, pharmacist, or personal physician can be questioned regarding the circumstances and events surrounding the illness, particularly the availability of chemicals and the likelihood of exposure. The patient’s clothes and place of discovery should be searched for such evidence and to bring it in for inspection.
In the absence of a history of exposure, the characteristic clinical course of poisoning may also suggest the diagnosis. Signs and symptoms of poisoning typically develop within minutes to an hour of an acute exposure, progress to a maximum within several hours, and gradually resolve over a period of hours to a few days. In such situations, toxicology screening may allow for a positive diagnosis if signs and symptoms are consistent with the known toxicity of the toxin(s) detected and other etiologies have been excluded.

Identification of the Offending Agent

History

The etiology of poisoning may or may not be disclosed by the patient history. Even when a history is available, its accuracy and reliability must be carefully assessed. The identity and amount of the toxin involved is frequently incorrectly reported by patients with intentional ingestions. Layperson misidentification of acetaminophen as aspirin and vice versa is relatively common. To avoid misdiagnosis, the presence or absence of both drugs should be confirmed by laboratory analysis when an overdose of any kind is suspected.

Pill, Product, Plant, and Animal Identification

Drugs in pill form can often be identified by the imprint code; the alphabetical and numeric markings on tablets and capsules. A listing of imprint codes with the corresponding trade name and ingredient(s) can be found in the Identidex portion of Poisindex [16], which is available at virtually all poison centers in the United States. It also provides the identities of street drugs based on their slang names. Prescription drugs may be identified by contacting the dispensing pharmacy. Drug samples can sometimes be identified by direct chemical analysis (see “Toxicology Screening” section). Police and government toxicology laboratories may be of assistance when illicit drug use is involved.

By US law [20], the ingredients of potentially hazardous commercial products used in and around the home must be stated on their labels. This information, however, is not always present or accurate, and labels may be missing or unreadable. In such cases, the ingredients may be identified by consulting Poisindex [16] or a regional poison center. Alternatively, the manufacturer or distributor may be called to obtain information. This may be particularly helpful when the product is an outdated formulation or a recently reformulated or released one. Most large companies maintain 24-hour emergency telephone numbers for such purposes, and many employ medical consultants to provide
management advice. Although industrial products do not have the same labelling requirements as household ones, right-to-know legislation requires that companies make information regarding the ingredients and potential toxicity of products they make, distribute, or use available to workers and health care providers. Such information can be obtained by requesting a Material Safety Data Sheet (MSDS).

Information on drugs and chemical products manufactured or obtained outside the United States can be found in Poisindex [16] and Martindale: The Complete Drug Reference [12], or obtained from a domestic or foreign poison center. Information on drugs undergoing clinical trials in the United States may also be found in Martindale, since such drugs are often already available in other countries. Most foreign poison centers have English-speaking staff or translators available.

Plants (including fungi or mushrooms), along with their active parts and chemical constituents, can be identified by consulting Poisindex [16] if either their common or botanical name is known. If the name is not known but a sample is available, a representative from a local nursery, horticultural or mycologic society, or university botany department may be of assistance in identifying it. Similarly, pet stores, zoos, veterinarians, amateur or academic entomologists, herpetologists, zoologists, and field guides can be helpful in identifying potentially venomous insects, reptiles, snakes, and other animals. Poison centers usually maintain lists of local experts who are willing to help with such identifications.

Toxidrome Recognition

A toxidrome is a clinical syndrome that involves multiple physiologic systems and facilitates bedside identification of the culprit toxin’s drug class. The physiological state of the patient can usually be characterized as excited (central nervous system [CNS] excitation with increased blood pressure, pulse, respirations, and temperature), depressed (decreased level of consciousness and decreased vital signs), discordant (inconsistent, mixed, or opposing CNS and vital sign abnormalities), or normal. The differential diagnosis can then be narrowed to the common or characteristic causes of these physiologic states (Table 97.3).

</tbody>
</table>
The excited state is primarily caused by sympathomimetics (agents that directly or indirectly stimulate α- and β-adrenergic receptors), anticholinergics (agents that block parasympathetic muscarinic receptors), hallucinogens, and withdrawal syndromes. The depressed state is primarily caused by sympatholytics (agents that block adrenergic receptors or depress cardiovascular activity), cholinergics (agents that directly or indirectly stimulate muscarinic receptors), opioids, or sedative hypnotics (which enhance the effect of the inhibitory CNS neurotransmitter γ-aminobutyric acid [GABA] or depress neuronal membrane excitability). The discordant state is primarily due to asphyxiants (agents that decrease the availability, absorption, transport, or use of oxygen), membrane active agents (those that block sodium channels or otherwise alter the activity of excitable cell membranes), and agents that cause a variety of CNS syndromes due to interference with dopamine, GABA, glycine, or the synthesis, metabolism, or function of serotonin. A normal physiological state may be due to a nontoxic exposure (Table 97.4), psychogenic illness, or presentation during the preclinical phase of poisoning. Agents that have a long preclinical phase (delayed onset of toxicity) are known as toxic “time bombs.” Delayed onset of toxicity may result from slow absorption or distribution, metabolic activation, or a mechanism of action that involves the disruption of metabolic or synthetic pathways. Psychogenic illness should be considered when symptoms are inconsistent with the reported exposure and cannot be substantiated by objective physical findings, laboratory abnormalities, and toxicologic testing and other etiologies have been excluded [21].

**TABLE 97.4 Criteria for a Nontoxic Exposure**

| Patient is asymptomatic by both history and | |
An excited or depressed state may be mischaracterized as a discordant one when the activity of a stimulant or depressant is selective for a receptor subtype or results in a compensatory or opposing autonomic response. For example, hypotension caused by an $\alpha$-blocker, $\beta_2$-agonist, or vasodilator may be accompanied by tachycardia, and hypertension due to a selective $\alpha$-agonist (phenylpropanolamine) may be accompanied by bradycardia. Severe stimulant or depressant poisoning can also cause what appears to be a discordant state (Table 97.5). For example, prolonged seizures and extreme hyperthermia caused by sympathomimetics can culminate in cardiovascular collapse as a consequence of anaerobic metabolism, acidosis, or depletion of neurotransmitters. Similarly, marked hypotension and hypoventilation caused by physiologic depressants can precipitate seizures and tachyarrhythmias as a result of ischemia, anoxia, and acidosis. In addition, paradoxic excitation can result from the preferential inhibition of cortical function that normally controls social activity by low doses of CNS depressants, most notably alcohol and other sedative hypnotics. In such cases, the physiologic state and its cause can often be correctly identified by the overall clinical picture and course of events.

### TABLE 97.5 Physiological Grading of the Severity of Poisoning

<table>
<thead>
<tr>
<th>Severity</th>
<th>Stimulant poisoning</th>
<th>Depressant poisoning</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Grade 1</strong></td>
<td>Agitation, anxiety, diaphoresis, hyperreflexia, mydriasis, tremors</td>

<tr>
<td><strong>Grade 2</strong></td>
<td>Confusion, fever, hyperactivity, hypertension, tachycardia, tachypnea</td>
<td>Mild coma (nonverbal but responsive to pain); brainstem and deep tendon reflexes intact</td>
</tr>
</tbody>
</table>
The severity of mental status changes and the nature of associated autonomic findings can be used to narrow the differential diagnosis of physiological stimulation and depression to one of four subcategories (see Table 97.3). For the excited patient, marked vital sign abnormalities (severe hypertension with end-organ ischemia, tachyarrhythmias, hyperthermia, and cardiovascular collapse) with minor mental status changes suggest an agent with peripheral sympathomimetic activity as the cause. Conversely, marked mental status abnormalities with nearly normal vital signs suggest a centrally acting hallucinogen. Anticholinergic poisoning (Table 97.6) can be differentiated from sympathomimetic (Table 97.7), hallucinogen, and withdrawal syndromes by the presence of dry, flushed, and hot skin; decreased or absent bowel sounds; and urinary retention. Other causes of excitation are usually accompanied by pallor, diaphoresis, and increased bowel or bladder activity.

Hypertension
Hyperthermia
Tachycardia

In the patient with physiological depression, marked cardiovascular abnormalities (hypotension and bradycardia) with relatively clear sensorium suggest a peripherally acting sympatholytic, whereas marked CNS and respiratory depression with minimal pulse and blood pressure abnormalities suggest a centrally acting agent (opioid or sedative hypnotic). Cholinergic poisoning (Table 97.8) can be distinguished from other causes of physiologic depression by the presence of characteristic autonomic findings: Salivation, lacrimation, urination, defecation, GI cramps, and emesis (SLUDGE syndrome). In addition, cholinergic poisoning causes pallor and diaphoresis, whereas the skin is usually warm and dry with opioid and sedative–hypnotic poisoning.

</thead>
</table>

Other findings can sometimes help narrow the differential diagnosis further. Only the most common and diagnostically useful ones are noted here. Because of limited specificity and sensitivity, the presence or absence of a particular sign or symptom cannot be used to confirm or exclude a given etiology.

Ocular findings can sometimes help narrow the diagnostic possibilities. Although mydriasis can be caused by any agent or condition that results in physiologic excitation (see Table 97.3), it is most pronounced in anticholinergic poisoning, in which it is associated with minimal pupil response to light and accommodation. Similarly, although miosis is a nonspecific manifestation of physiological depression, it is usually most pronounced in opioid poisoning. Notable miosis can, however, also be caused by cholinergic agents and sympatholytics with α-blocking effects.
(e.g., phenothiazines). Visual disturbances suggest anticholinergic,
cholinergic, digitalis, hallucinogen, methanol, and quinine poisoning.
Horizontal nystagmus and disconjugate gaze are nonspecific
manifestations of sedative–hypnotic poisoning. Although vertical and
rotary nystagmus can be seen in patients with lithium and phenytoin
poisoning, they are classical findings of phencyclidine intoxication. These
etiologies should be readily distinguishable by assessing the physiological
state. Rapidly alternating lateral “ping-pong” gaze has been described in
monoamine oxidase inhibitor poisoning. Except for abnormalities due to
topical chemical exposure, both eyes are equally affected. Although
failure to respond to topical miotics has been said to be diagnostic of
drug-induced pupillary dilatation, this is only true for topical exposures.
Hence, unilateral pupillary abnormalities should generally prompt
evaluation for a central, structural lesion.

Dermatological abnormalities may also be helpful. Flushed skin can be
caused by anticholinergics, boric acid, a disulfiram–ethanol reaction,
monosodium glutamate, niacin, scombroid (fish poisoning), and rapid
infusion of vancomycin (red man syndrome). The skin is hot and dry in
anticholinergic poisoning, but normal or moist with other etiologies.
Flushing should not be confused with the orange skin discoloration
caused by rifampin. Pallor and diaphoresis may be due to cholinergics,
hallucinogens, hypoglycemics, sympathomimetics, and drug withdrawal
(see Table 97.3). As noted previously, manifestations of the SLUDGE
syndrome distinguish cholinergic poisoning from other etiologies.
Cyanosis may be due to agents that cause cardiovascular or respiratory
depression, methemoglobinemia, pneumonitis, or simple asphyxia. For
methemoglobinemia, skin may have a slate-gray hue that is unaffected by
oxygen administration. Cyanosis should not be confused with the blue
discoloration of the skin caused by amiodarone or by topical exposure to
blue dyes. The latter condition can be diagnosed by wiping the skin with
acetone or alcohol. Hair loss, mucosal pigmentation, and nail
abnormalities are suggestive of heavy metal poisoning (arsenic, lead,
mercury, and thallium).

Finally, the presence of neuromuscular abnormalities may suggest
certain etiologies. Seizures and tremors can be caused by cholinergics,
hypoglycemic agents, lithium, membrane-active agents, some narcotics
(meperidine, propoxyphene), and stimulants (see Table 97.3). They can
also occur in patients poisoned by agents that cause asphyxia, low lactate
increased anion gap metabolic acidosis (AGMA; see later), and cerebral
hypoperfusion or hypoventilation (physiologic depressants; see Table
The most common causes of seizures due to poisoning are tricyclic antidepressants, sympathomimetics, antihistamines (primarily diphenhydramine), theophylline, and isoniazid. Although carbon monoxide, hypoglycemics, lithium, and theophylline can cause focal seizures, seizures due to poisoning are usually generalized. Because hypertensive and traumatic CNS hemorrhages are known complications of poisoning, the possibility structural lesions should always be considered. Myoclonus suggests anticholinergic, sympathomimetic poisoning, or Serotonin syndrome. Fasciculations are typical of cholinergic insecticide poisoning but can also be caused by sympathomimetics. Rigidity may be seen in phencyclidine and sympathomimetic poisoning and in those with CNS syndromes (see Table 97.3). Dystonic posturing is most often caused by antipsychotic agents. It is also a characteristic feature of strychnine poisoning.

**Laboratory Findings**

Acid–base status, anion gap, serum osmolality, ketone, electrolyte, glucose, and organ function abnormalities identified by routine laboratory tests can be extremely helpful in the differential diagnosis of poisoning. As with clinical manifestations, the diagnostic sensitivity and specificity of a single finding is not sufficiently high for its presence or absence to confirm or exclude a specific etiology. The use of anion and osmolar gaps and serum ketone and lactate levels in the diagnosis of poisoning of unknown etiology is summarized in Figure 97.1.

**FIGURE 97.1** Use of routine laboratory findings and calculated gaps in the differential diagnosis of poisonings. AKA, alcoholic ketoacidosis; DKA, diabetic ketoacidosis; NRTI, nucleoside/nucleotide reverse transcriptase inhibitors.
Assessing acid–base status and calculating the anion gap is particularly important because an increased AGMA may be due to advanced ethylene glycol, methanol, and salicylate poisoning. In such cases, prompt initiation of specific therapies is essential to prevent progressive, irreversible, or fatal poisoning [22]. The normal anion gap is $13 \pm 4 \text{ mEq per L}$ in unselected acutely hospitalized patients. In ethylene glycol and methanol poisoning, AGMA is primarily due to the accumulation of acid metabolites. In salicylate poisoning, it is caused by the accumulation of a variety of endogenous organic acids resulting from salicylate’s interference with intermediary metabolism. Agents that cause hypoxemia, cellular asphyxia, seizures, shock, or extensive tissue necrosis can also cause an AGMA, but in these instances, the accumulation of lactic acid generated by anaerobic metabolism is responsible for the AGMA. When the underlying cause is unclear, measuring the serum lactate level may be helpful. The lactate concentration is usually low ($<5 \text{ mEq per L}$) or significantly less than the anion gap in ethylene glycol, methanol, and salicylate poisoning, but higher in conditions associated with anaerobic metabolism.

Other common toxicologic causes of a low-lactate AGMA include ethanol, which can cause ketoacidosis by disrupting intermediary metabolism in susceptible alcoholics, and toluene, which can cause renal tubular acidosis with bicarbonate wasting. Rarely, this metabolic picture occurs in poisoning by formaldehyde (which is metabolized to formic acid), paraldehyde (presumably as a result of its metabolism to acetic acid), phosphate, and sulfur (and possibly sulfates). It can also be seen with large overdoses of ibuprofen (and probably all nonsteroidal anti-inflammatory agents) and valproic acid (due to high levels of these acidic drugs and their metabolites). Metformin and nucleoside reverse transcriptase inhibitor antiretroviral agents (e.g., zidovudine or azidothymidine) can interfere with normal-lactate metabolism and cause a high-lactate AGMA at therapeutic as well as excessive doses. A high-lactate AGMA can occur soon after massive acetaminophen ingestion [23].

An abnormally low anion gap may be seen in severe bromide, calcium, iodine, lithium, magnesium, and nitrate intoxication [24]. In bromide, iodine, and lithium intoxication, the low anion gap results from spuriously elevated chloride levels, and with nitrate poisoning, it is due to falsely elevated bicarbonate levels.

Serum osmolality can help differentiate the toxic causes of a low-lactate AGMA. An increased osmole gap may be seen early in the course of
ethylene glycol and methanol (when high serum levels of the parent compounds are present) but not salicylate poisoning. Although not strictly accurate from a physical chemistry perspective [25], the osmole gap is typically defined as the difference between the measured serum osmolality and the calculated serum osmolality.

\[
\text{Serum Osmolality (µmol/L)} = 2 \times (\text{serum Na}) + \text{serum glucose} + \text{serum BUN}
\]

where normal serum osmolality is 290 ± 10 mOsm per kg of H\textsubscript{2}O normal osmole gap is 5 ± 7 mOsm per kg (in unselected acutely hospitalized patients [22]).

Osmole gap = [calculated serum osmolality – measured serum osmolality]

Normal osmole gap is 5 ± 7 mOsm per kg (in unselected hospitalized patients [22]).

This formula assumes that all concentrations are measured in millimoles per liter. If the glucose and BUN concentrations are measured in milligrams per deciliter, dividing them by 18 and 3, respectively, gives their approximate concentrations in millimoles.

Additional causes of an increased osmolar gap include other low-molecular-weight solutes, such as acetone, ethanol, isopropyl alcohol, magnesium, mannitol, and propylene glycol [26]. The approximate concentration of these substances that will increase the serum osmolality by 1 mOsm per kg of H\textsubscript{2}O, calculated on the basis of their molecular weights, is shown in Table 97.9. When direct measurements are not readily available, the serum concentration of these agents can be estimated by multiplying this amount by the osmolar gap. Serum osmolality must be measured by freezing point depression (rather than the headspace or vapor pressure method) to detect the presence of volatile agents such as acetone and toxic alcohols. An increased osmolar gap can be seen in alcoholic ketoacidosis and other conditions causing lactic acidosis.

Serum ketones can also help to differentiate the toxic causes of a low-lactate AGMA. Ketosis, as defined by a positive nitroprusside reaction, is relatively common in salicylate poisoning but unusual in ethylene glycol and methanol poisoning. Ketosis is also seen in alcoholic ketoacidosis and in acetone or isopropyl alcohol poisoning.

The urinalysis, serum calcium concentration, and the overall clinical picture can also be helpful in differentiating the toxic causes of a low-lactate AGMA. Crystalluria, hypocalcemia, and back pain or flank tenderness suggest ethylene glycol; visual symptoms implicate methanol; and tinnitus or impaired hearing point to salicylates. Crystalluria can also be caused by acyclovir [27], felbamate [28], indinavir [29], oxalate [18], primidone [19], and sulfa drugs [30]. Hypocalcemia is also seen in fluoride and oxalate [18] intoxication.

Serum potassium and glucose abnormalities may also provide clues to the etiology of the poisoning [11]. Toxicologic causes of hypokalemia include barium, \( \beta_2 \)-adrenergic agonists, calcium channel blockers, chloroquine, diuretics, insulin, licorice, methylxanthines, and toluene. Hyperkalemia can be caused by \( \alpha \)-adrenergic agonists, angiotensin-converting enzyme inhibitors, \( \beta \)-blockers, digitalis, fluoride, potassium-sparing diuretics, and trimethoprim. Common toxicologic causes of hypoglycemia are ethanol, \( \beta \)-blockers, hypoglycemics, quinine, and salicylate. Common causes of hyperglycemia include acetone, \( \beta \)-agonists, calcium channel blockers, iron, and methylxanthines.

Common toxicologic causes of acute liver dysfunction are
acetaminophen, ethanol, halogenated hydrocarbons (carbon tetrachloride), heavy metals, and mushrooms (*Amanita phalloides* and related species). Acute renal toxicity is most often due to ethylene glycol, halogenated hydrocarbons, heavy metals, nonsteroidal anti-inflammatory drugs, toluene, envenomations, and agents that cause hemolysis or rhabdomyolysis. An elevated creatinine with a normal BUN can be seen in acetone and isopropyl alcohol poisoning because acetone interferes with colorimetric assays for creatinine, resulting in falsely high results. Acute hemolysis (in the absence of glucose-6-phosphate dehydrogenase deficiency) can result from poisoning by arsine gas, naphthalene, and inducers of methemoglobinemia. Rhabdomyolysis is associated with toluene abuse, CNS syndromes (see Table 97.3), and severe physiological dysfunction (extreme agitation, deep or prolonged coma, hyperthermia, and seizures) of any etiology. The most common agents involved are sympathomimetics, ethanol, and MDMA.

**Electrocardiographic Findings**

The ECG may provide clues to the cause of poisoning [11]. Ventricular tachyarrhythmias that occur in patients with normal QRS and QT intervals suggest myocardial irritation (increased automaticity) as the underlying mechanism. Sympathomimetics, digitalis, and cardiac-sensitizing agents such as chloral hydrate and aliphatic or halogenated hydrocarbons, which potentiate the action of endogenous catecholamines, are potential causes. In contrast, ventricular tachyarrhythmias that occur in the setting of depolarization and repolarization abnormalities, reflected by QRS and QT interval prolongation, respectively, suggest a reentrant mechanism. Causes include electrolyte abnormalities, organophosphate insecticides, and other membrane active agents (see Table 97.1). Torsades de pointes (polymorphous) ventricular tachycardia strongly implicates a QTc prolonging agent.

Atrioventricular conduction abnormalities and bradyarrhythmias can be caused by β-blockers, calcium channel blockers, digitalis, membrane-active psychotherapeutic agents, organophosphate insecticides, and α-agonists such as phenylpropanolamine.

**Radiographic Findings**

Ingested chemicals can sometimes be visualized within the GI tract by
abdominal radiographic imaging, and such imaging can occasionally be helpful in suggesting the etiology or amount of an unknown ingestion. Agents most likely to be visible on plain films are indicated by the mnemonic CHIPES (Table 97.10) [11].

Ingested drug packets may appear as uniform, marble-sized densities scattered along the GI tract [31,32]. Ingested hydrocarbons may sometimes appear as a double gastric fluid level or “double bubble” because of the air–fluid and fluid–fluid interface lines created when less dense hydrocarbons layer on top of gastric fluids. Computed tomography may be superior to plain films in detecting ingested drug packets but the optimal test in this setting remains unclear [33]. Whether or not contrast should be used remains controversial. Abdominal ultrasound can detect ingested pills, particularly enteric-coated and sustained-released formulations. Such imaging may be useful in confirming or refuting some recent specific (CHIPES) ingestions. Because the volume of pills can be determined, plain radiography may be used to guide GI decontamination.

Abnormal findings on chest radiography can be caused by a wide variety of chemicals [11]. Diffuse or patchy infiltrates (pneumonitis or acute lung injury) can be due to the inhalation of irritant gases (ammonia, chlorine, hydrogen sulfide, nitrogen oxides, phosgene, smoke, and sulfur dioxide), fumes (beryllium, metal oxides, and polymers), and vapors (acids, aldehydes, hydrocarbons, isocyanates, and mercury). They can also be seen among patients who have ingested or injected cholinergic agents (carbamate and organophosphate insecticides), metabolic poisons (cyanide, carbon monoxide, heavy metals, and hydrogen sulfide), paraquat, phencyclidine, salicylates, thiazide diuretics, and tocolytics, and in patients with envenomations. Aspiration pneumonitis is quite common and can occur in patients with coma or seizures. Acute lung injury can also develop among patients with prolonged or pronounced anoxia, hyperthermia, or hypotension. Chronic chemical exposure can cause pulmonary fibrosis, granulomas, or pleural
Response to Antidotes

The use of antidotes for diagnostic purposes has largely fallen from favor. The availability of point of care blood glucose measurement negates the need for empiric intravenous dextrose in altered patients. Many antidotes may be harmful if used inappropriately, including flumazenil, physostigmine, glucagon, nitrites, chelators, and lipid emulsions. Naloxone remains a reasonably safe therapy for a patient with clinical signs of opiate intoxication. Clinicians should be prepared to manage acute withdrawal and its sequelae.

Toxicology Screening

Analyses of a sample of the toxin itself, or patient urine, blood, or gastric contents can sometimes be helpful for identifying the cause of poisoning. Urine is generally the best specimen to analyze, because large quantities can be obtained for extraction procedures and many chemicals are concentrated in urine. However, toxicology testing can detect only a small fraction of all chemicals (primarily drugs) and is not always reliable. Immunoassay screens are inexpensive and provide results within minutes, but they are only capable of detecting a few agents. They suffer from many false positives and false negatives. Patients may be misdiagnosed and potentially harmed by clinicians acting solely on the results of immunoassay screens [34]. Comprehensive screens are expensive and require 2 to 6 hours for completion (excluding transportation times). Although results may increase diagnostic certainty or specificity, they rarely change disposition or treatment in patients who are asymptomatic or who have signs and symptoms consistent with the reported exposure [34–37]. Noteworthy exceptions are acetaminophen and salicylate, which are widely available, commonly ingested, sometimes misidentified, require specific treatment, and cause few or nonspecific early signs and symptoms. Hence, in most overdose patients, quantitative acetaminophen and salicylate levels are the only screening toxicology tests likely to be clinically useful.

Critically ill poisoned patients suffering seizures, cardiovascular instability, acid–base abnormalities, multiple-organ dysfunction, nonsinus cardiac rhythms, or cardiac conduction disturbance without a toxicologic diagnosis should generally have comprehensive toxicology screening.

Knowledge of the methods used for chemical detection (colorimetric spot tests, thin-layer chromatography, gas or high-pressure liquid chromatography, absorbance, atomic absorption, flame ionization, or
fluorometric assays, enzyme-multiplied and radionuclide immunoassays, and gas chromatography with mass spectrometry) is required for optimum interpretation of screening tests results [21,34,38]. A positive result on one assay should always be confirmed by repeat analysis using a different technique. The physician should communicate directly with the laboratory technician to determine which chemicals can be detected by the screening methods used and the sensitivity and specificity of each assay. In addition, directed analysis (coma, hallucinogen, or stimulant screen), with more rapidly available results, can be performed when the technician and clinician communicate.

A negative result from a screen should never be used to exclude the diagnosis of poisoning when clinical findings suggest otherwise. It may simply mean a chemical is not detectable by the assay(s) used, its concentration is below the limit of detection of the assay(s), or its concentration is too low to be confirmed. It may also mean the timing of sampling or the specimen submitted is inappropriate for testing (the chemical may be undergoing absorption and is not yet present in urine or it may already have been metabolized or eliminated). In such cases, repeating the test on a sample obtained at an earlier or later time may be revealing.

**Prediction of Potential Toxicity**

The prediction of toxicity requires knowledge of the dose, time, and identity of an exposure and helps optimize treatment. For commercial products, the amount and concentration of every ingredient should be identified. Household products deemed hazardous by the US Consumer Product Safety Committee are required by law to bear a label describing the nature of their toxicity and first aid measures as well as a “keep out of reach of children” warning and a signal word that indicates the degree or severity of potential toxicity [20]. The signal words “caution,” “warning,” and “danger” identify a product or its constituent(s) as a weak irritant (may damage mucosal surfaces), strong irritant (can damage skin and mucosa), or corrosive (can cause permanent tissue damage or death) after topical exposure or moderately toxic, highly toxic, or extremely toxic (oral median lethal dose: 50 to 500 mg per kg, 1 to 50 mg per kg, or <1 mg per kg, respectively) after ingestion. Label information is frequently inaccurate or incomplete [20] and should generally be confirmed by consulting an independent information source.

The dose of drug in a pill or tablet can be determined using the
resources cited in “Identification of the Offending Agent” section of this chapter. For liquids and powders, the dose can be estimated or measured using the container or the weights and volumes listed on the label. An exposure may also be reported in tablespoons or swallows. Standard flatware volumes can vary from 3 to 7 mL for a teaspoon and from 7 to 14 mL for a tablespoon. The volume of a swallow varies with age, height, weight, sex, the orifice size of the container, and the viscosity of the ingested liquid and ranges from 1 to 5 mL in infants to 4 to 40 mL in adults [39].

The accuracy and reliability of the history must be evaluated when assessing potential toxicity. The amount and time of ingestion are frequently erroneous when reported by patients with intentional self-poisoning. It is always best to assume a worst-case scenario: that the maximum possible dose (the entire amount available or not clearly accounted for) was ingested. The potential toxicity can then be estimated from previously reported toxicodynamic data. For drugs with CNS and cardiovascular activity, the ingestion of 5 to 10 therapeutic doses by an adult and one adult dose by a young child can result in significant toxicity. β-Blockers, calcium channel blockers, and oral hypoglycemics can cause toxicity after only one or two therapeutic doses, particularly in those physiologically naive to their effects. The ingestion of only one to two tablets, capsules, or teaspoonfuls of an antimalarial (chloroquine, hydroxychloroquine), antipsychotic, camphor, calcium channel blocker, methyl salicylate, opioid, oral hypoglycemic, theophylline, or tricyclic antidepressant can be fatal to a toddler [40].

The time of exposure is important because it helps to predict the times of toxicity onset and of peak toxicity. Only when the time elapsed since exposure clearly exceeds the longest reported or predicted interval between exposure and peak toxicity should the possibility of subsequent poisoning be excluded (see Table 97.5). Peak toxicity usually occurs within 4 to 6 hours of an oral overdose. Important exceptions to this generalization are the toxic time bombs described earlier. For some of these agents (acetaminophen, ethylene glycol, methanol, and paraquat), the serum concentration measured during the preclinical phase can be used to predict subsequent toxicity. Peak toxicity may also be delayed (up to 12 to 24 hours) after exposure to irritants and corrosives. The possibility of pregnancy and potential toxicity to the fetus should also be considered.

Assessment of Severity

The severity of poisoning is primarily determined by the clinical picture. Because poisoning is far more dynamic than most diseases and illnesses, frequent reevaluations are required. Poisoned patients can rapidly
deteriorate, with few or no warning signs.

A complete physical examination should be performed in all patients. The examination should initially be directed toward assessment of cardiovascular stability, respiratory function, and neurologic status. Accurate and timely measurement of all vital signs is essential. The respiratory rate should be measured accurately. A core temperature should be obtained to detect severe or occult abnormalities. The most severe patients are most likely to have significant temperature abnormalities. Preoccupation with their cardiovascular and respiratory therapy may lead to delayed temperature measurement. An abbreviated mental status examination is usually sufficient.

The number and type of ancillary tests required to assess metabolic or organ function is determined primarily by clinical severity and secondarily by the history. Asymptomatic but potentially poisoned patients with reliable histories and unintentional exposures should have blood and urine samples obtained on presentation. Samples can be saved and subsequently sent for (baseline) analysis in the event of deterioration. Pregnancy testing is recommended in all susceptible women of childbearing age. Patients who are symptomatic or suicidal should have serum electrolytes, BUN, creatinine, glucose, urinalysis, and 12-lead ECG. Arterial blood gas, serum osmolality, and ketone and methemoglobin analyses may be indicated. Anion, osmolal, and oxygen saturation gaps should be calculated whenever their determinants are measured. Assessment of patients with respiratory complaints or grade 2 or greater stimulant or depressant poisoning (see Table 97.5) should include a chest radiograph. A complete blood cell count, coagulation studies, serum amylase, calcium, magnesium, creatine phosphokinase, and hepatic enzyme levels should also be determined in any patient with grade 2 or greater physiological dysfunction. Additional testing should be individualized and based on the history, physical examination findings, and the results of routine ancillary studies.

The measurement of chemical concentrations in serum or urine can sometimes help in assessing the severity of poisoning. Agents for which quantitative measurements are necessary or desirable for optimal patient management include acetaminophen, acetone, alcohols, antiarrhythmics, antiepileptics, barbiturates, carbon monoxide, digoxin, electrolytes (including calcium and magnesium), toxic alcohols, heavy metals, lithium, salicylate, and theophylline [21,34]. Quantitative or qualitative assays for other toxins are not generally helpful because they serve only to confirm the clinical impression and do not affect treatment (which is either supportive or must be initiated long before laboratory results are available in order to be effective).

Provision of Supportive Care
Meticulous supportive care is necessary to maintain physiological and biochemical homeostasis and to prevent secondary complications (anoxia, aspiration, and secondary organ injury) until detoxification is complete. Despite advances in preventing absorption, enhancing elimination, and antidotal treatment, supportive care remains the mainstay of therapy for most poisoned patients. Details of supportive therapy by organ system can be found in the delineated chapters. Only considerations of special relevance to the poisoned patient are discussed here.

**Monitoring**

Unless toxicity is minimal and predicted with a high degree of certainty to remain so, venous access should be established and continuous cardiac monitoring initiated. Pulse oximetry should be performed on presentation and monitored frequently if abnormal or significant (grade 2 or greater) physiologic dysfunction (see Table 97.5) is present. Until the ultimate severity of poisoning is known, frequent or continuous visual observation is also necessary. Patients with intentional self-poisoning also need close behavioral observation until the possibility of a repeat suicide attempt has been evaluated in detail and assessed to be unlikely.

**Respiratory Care**

Aspiration of gastric contents is a relatively common complication of poisoning and its treatment (during GI decontamination procedures). Patients with CNS depression or seizures are at particularly high risk. For patients deemed high risk for aspiration, or whose clinical conditions are likely to progress to requiring airway protection, endotracheal intubation should be performed early. Prophylactic or therapeutic intubation may also be required for patients with extreme behavioral agitation or physiological overactivity who require aggressive pharmacologic therapy with a sedative, antipsychotic, anticonvulsant, or the combination of a neuromuscular blocking agent with a sedative.

**Cardiovascular Therapy**

Because of adverse drug interactions, therapy intended to maintain or restore normal blood pressure, pulse, and sinus rhythm may paradoxically worsen cardiovascular toxicity. Hence, the severity and trend of cardiovascular abnormalities and the potential complications of
treatment should be considered before instituting pharmacological therapy. In addition, because the causes of cardiovascular toxicity are varied and multiple mechanisms may be concurrently operative, invasive hemodynamic monitoring may be necessary for accurate diagnosis and optimal treatment. Aggressive supportive measures, such as transvenous cardiac pacing and intra-aortic balloon pump or extracorporeal membrane oxygenation should be considered in patients with reversible poisoning who are unresponsive to less aggressive therapeutic measures [41]. Intoxicated patients tend to deteriorate more quickly than standard ICU patients, so the necessary consults to initiate ECMO should be made as early as possible. The required duration of ECMO will be much shorter for intoxicated patients than for other ICU patients.

In the absence of extremes of heart rate, hypotension due to poisoning is most often caused by loss of peripheral vascular tone rather than pump failure. Bedside echocardiography can also be useful to assess cardiac output. Norepinephrine is generally considered the first line vasopressor for patients who do not respond to fluid administration.

When hypertension causes end-organ dysfunction, therapy is indicated. For patients with sympathomimetic poisoning, β-blockade may result in unopposed α-receptor stimulation. This leads to increased peripheral vascular resistance, increasing the demand on a β-blocked heart. Hence, treatment with a nonselective sympatholytic or with an arteriodilator followed by a β-blocker is preferred.

Sinus tachycardia can usually be managed with sympatholytics. In patients with sympathomimetic poisoning and signs or symptoms of myocardial ischemia, a β-blocker (with or without an arteriodilator, depending on the presence or absence of coexisting hypertension) or a calcium channel blocker can be used.

Amiodarone is generally first line therapy for ventricular tachyarrhythmias. Underlying electrolyte and metabolic abnormalities should be corrected. Sodium bicarbonate or hypertonic saline may be effective in treating wide-complex tachycardias due to toxins with sodium channel blocking properties.

Normalizing electrolytes and continuous electrocardiographic monitoring is the mainstay of treatment for toxins that prolong the QT interval. The clinician must be prepared to manage Torsades des Pointes. Antibodies are available to treat serious dysrhythmias caused by cardiac glycosides. Magnesium may also be effective in digitalis poisoning. Procainamide, other class 1 A agents (including Phenytoin), β-blockers, and physostigmine should not be used for arrhythmias caused by membrane-active agents or those associated with prolonged QRS or QT intervals because of the potential for worsening rhythm disturbances and conduction abnormalities.

Bradycardia requires treatment only if it is associated with
hemodynamic instability. In most cases, atropine, dopamine, and epinephrine are the agents of choice. Glucagon, Calcium, high dose insulin, and lipid therapy can be effective in β-blocker poisoning. Calcium, high dose insulin, and lipid therapy can be effective in calcium channel blocker poisoning.

**Treatment of Neuromuscular Hyperactivity**

Profound metabolic acidosis and sudden cardiac arrest can occur in patients with severe agitation who continue to struggle while being physically restrained. Prompt pharmacologic treatment of behavioral and muscular hyperactivity in such patients is critical. In general, benzodiazepines are preferred to antipsychotic agents because the latter lower the seizure threshold and prolong QTc. We have decades of experience and safety data supporting the use of benzodiazepines in this setting. For agitation and hallucinations due to anticholinergic poisoning, physostigmine may be considered.

Seizures can usually be effectively treated with GABA agonists such as benzodiazepines or propofol. Pyridoxine is usually necessary in isoniazid poisoning. Phenytoin, a Vaughn–Williams class 1 anticonvulsant, should be avoided in all cases where a toxin with sodium channel blocking properties may have been ingested. Seizures due to cyanide, hydrogen sulfide, and organophosphate insecticides usually require specific antidotes. Please see Chapter 151 for detailed discussion of the treatment of seizures.

Severe agitation or prolonged convulsions can also cause rhabdomyolysis and hyperthermia. Because these complications can result in additional organ dysfunction, neuromuscular blocking agents should be given to patients after they do not respond to sedatives alone. During such therapy, vigilant monitoring for seizures is important (electroencephalography is recommended) because urgent effective treatment can prevent permanent neurologic damage.

**Prevention of Absorption**

Early and effective decontamination can limit the surface exposure and systemic absorption of chemicals and reduce toxicity. Decontamination should be considered in all patients unless the exposure is clearly nontoxic (see Table 97.4), the time of predicted peak toxicity has passed, or the benefit of decontamination is minimal.

**Body Cavity Exposure**

The removal of chemicals from body cavities (bladder, external auditory
canal, nose, rectum, and vagina) can be accomplished by aspiration and irrigation using normal saline. Particulate matter (pills, suppositories, and drug packages) should be manually removed, preferably under direct visualization. The removal of ingested drug packages from the GI tract is discussed in “Ingestion” section of this chapter.

**Eye and Skin Exposure**

Decontamination after topical exposure includes manual removal of particulate material, irrigation of exposed surfaces, and a scrub for skin exposed to noncorrosive chemicals. Because “time is damage,” particularly with corrosives, tap water or any other readily available liquid that is clear and drinkable can be used in the prehospital setting. If exposure involves an unknown chemical, its pH should be measured. Searching for pH paper (pHydrion), usually available in the emergency department or the labor and delivery area, should not delay treatment. Irrigation should initially be performed for about 20 minutes. Prolonged irrigation (up to 24 hours) may be beneficial for corrosive exposures, especially those involving strong alkali.

With ocular exposures, blepharospasm secondary to pain can prevent effective irrigation unless treatment is preceded by the instillation of a topical anesthetic. Particulate material should be removed with a moist cotton-tipped swab or eye spud. Normal saline and lactated Ringer’s solution are traditionally used irrigation fluids. Irrigating solutions can be administered via an IV infusion setup, directly through the tubing, or via an irrigating (Morgan) lens attachment. A low-pressure squeeze bottle also may be used. One or two liters is usually sufficient. For acid or alkali exposures, the tear pH (normally 7.3 to 7.7) should be determined before and after irrigation. Irrigation should continue until the pH is between 5 and 8.

For skin exposures, treatment should begin with the removal of contaminated clothing. Gloves should be worn to prevent contamination of caretakers. Particulate matter should be removed from the skin using a soft brush, forceps, or hand-held vacuum cleaner before irrigation. Washing the skin with soap and water or isopropyl alcohol more effectively prevents pesticide absorption than using water alone. For some toxins, a triple wash (irrigation and washing with soap before and after an alcohol scrub) may provide better decontamination than irrigation alone.
Ingestion

GI decontamination can be accomplished with activated charcoal, gastric lavage, whole-bowel irrigation, and endoscopic or surgical removal of the ingested chemical. There is little to no role for Ipecac [42,43]. Cathartics, although previously used in conjunction with other treatments, are not an effective method of decontamination [44]. Except for cases of corrosive ingestion, the same is true for diluents.

Despite extensive experimental data documenting the efficacy of GI decontamination measures for preventing chemical absorption in animals and in human volunteers, there is no conclusive evidence that these interventions improve the outcome in actual overdose patients [42,44–48]. Clinical efficacy is difficult to prove because the overdose history is frequently unreliable, and most overdoses do not cause severe or life-threatening toxicity. In addition, the efficacy of GI decontamination decreases as the time between ingestion and treatment increases. Experimental data showing that GI decontamination is effective in preventing chemical absorption when initiated more than 1 hour after ingestion is limited. Since the mean time between ingestion and arrival at a hospital is more than 1 hour in children and more than 3 hours in adults [49–52], most patients present for treatment at a time when the efficacy of GI decontamination remains unproven.

With the sophisticated monitoring and supportive techniques available today, it is more likely that most poisoned patients will recover fully without any decontamination therapy [51]. However, since experimental studies show that decontamination can limit toxin absorption and shorten the duration of toxicity, and since absorption is prolonged after overdose, decontamination may be effective longer after ingestion than experimentally proven. It is therefore recommended that it be performed unless the exposure is nontoxic (see Table 97.4), or the risk of decontamination outweighs the potential benefit.

The choice of decontamination method should be based on the relative efficacy, and contraindications of the available options. Activated charcoal has equal or greater efficacy, fewer contraindications, less frequent and less serious complications than other methods of decontamination, and is the preferred treatment for most overdoses [48–53]. Emptying the stomach via lavage has rare, specific indications.

Gastric lavage is indicated for recent life-threatening ingestions, when the toxin is small in size or easily dissolved in the stomach, not well adsorbed by activated charcoal and not responsive to other therapies. Whole-bowel irrigation should be considered for patients who have ingested toxic amounts of agents that are slowly absorbed or not amenable to decontamination by other techniques. Endoscopy and surgery should be reserved for patients with potentially severe poisoning.
in whom alternative methods of decontamination are unsuccessful or contraindicated.

Activated Charcoal. Activated charcoal can prevent absorption of ingested chemicals by binding them within the gut lumen. Its clinical efficacy remains controversial [48] because it is neither absorbed nor metabolized, the toxin bound to it is normally eliminated with stool [47,54]. Activated charcoal is a fine black powder produced by the activation (pyrolysis, oxidation, and purification) of carbon-containing materials such as bone, coal, peat, petroleum, and wood. It is odorless, tasteless, and insoluble in liquids. The activation process yields particles that have an extensive internal network of minute, branching, irregular, interconnecting channels that range in size from approximately 10 to 100 nm in diameter and account for the extremely large surface area of activated charcoal. The surface area of activated charcoal in clinical use ranges from 600 to 2,000 m² per g.

The absorption or adherence of chemical molecules to the external and internal surfaces of activated charcoal is rapid (within minutes of contact). It is due to relatively weak van der Waals forces and can be described by the following reversible equilibrium: activated charcoal + toxin ↔ activated charcoal – toxin complex. Hence, as the amount of activated charcoal is increased, the fraction of unbound or free chemical decreases (the equilibrium shifts to the right according to the law of mass action). At an activated charcoal to chemical ratio of 10 to 1 or greater, 90% or more of most chemicals is adsorbed into charcoal in vitro. The absorptive capacity (the amount of chemical that can be absorbed by 1 g of charcoal in vitro) ranges from a few milligrams to more than 1 g depending on the molecular size, structure, and solubility of the chemical, the pore size and surface area of activated charcoal, the negative logarithm of acid ionization constant of the chemical and the pH of the solution, and the presence or absence of competing solutes. Small, highly ionized molecules of inorganic compounds, such as acids, alkali, electrolytes, and the readily dissociable salts of arsenic, bromide, cyanide, fluoride, iron, and lithium, are not well adsorbed by activated charcoal [54].

In animal studies and in simulated overdoses using therapeutic or slightly greater doses in human volunteers, activated charcoal prevents the GI absorption of nearly all chemicals [55]. In agreement with in vitro studies, as the ratio of activated charcoal to chemical increases, its efficacy increases; with simultaneous dosing of activated charcoal and chemical at a ratio of 10 to 1 or greater, charcoal prevents the absorption of most chemicals by more than 90%. At a constant charcoal to chemical ratio, the efficacy of activated charcoal in preventing chemical absorption increases as the amount and concentration of either agent increases.
Previous studies [54,55] suggest that the efficacy of activated charcoal may be relatively greater after actual overdose than it is after a simulated one. Diluting a dose of activated charcoal and administering it in aliquots by gastric lavage is less effective than administering the same dose as a single concentrated bolus [54]. Administering a dose before and after gastric lavage is more effective than giving one only after lavage.

The interval between administration of toxin and activated charcoal also has a significant effect on the in vivo efficacy of charcoal. As this interval increases, the ability of activated charcoal to prevent chemical absorption decreases. In controlled studies using doses of activated charcoal many times greater than those of toxin, charcoal decreased chemical absorption an average of 71% (range 10% to 100%) when it was given within 5 minutes, 52% (range 17% to 75%) when given at 30 minutes, and 38%, 34%, 21%, 29%, and 14% when given at 1, 2, 3, 4, and 6 hours, respectively [47].

The ability of activated charcoal to prevent the absorption of a toxin in vivo generally correlates with its ability to absorb that chemical in vitro [55]. However, the absorption of some toxins that are poorly adherent to activated charcoal (e.g., cyanide, malathion, and tolbutamide) is significantly reduced. Conversely, the absorption of some toxins that are relatively adherent to activated charcoal in vitro (ethanol, ipecac, and N-acetylcysteine) is not significantly inhibited in vivo. The presence of food in the stomach appears to enhance the efficacy of activated charcoal in preventing the absorption of ingested agents, possibly by slowing gastric emptying. Coingested antacids, cathartics, chocolate, ethanol, and excipients have variable but relatively minor or no effect on its efficacy.

Activated charcoal is administered as an aqueous suspension; a minimum of 8 mL of water should be added to each gram of powdered charcoal if a premixed formulation is not available. Premixed product containers should be thoroughly agitated to resuspend sedimented charcoal before use.

Activated charcoal can be given orally to awake patients or by gastric tube to comatose or uncooperative patients. A nipple bottle can be used for infants. The recommended dose is at least 10 times the weight of the ingested toxin. Because of volume constraints, the maximum single dose is generally limited to 1 to 2 g per kg of body weight.

Compared with other methods of GI decontamination, the advantages of activated charcoal are ease of administration, rapidity of action, extensively documented safety and efficacy, lack of absolute contraindications, and its ability to enhance toxin elimination (see
“Multiple-Dose Activated Charcoal” section of this chapter). The main disadvantages are its dark color (significantly impairs bronchoscopy if aspirated), and low or reversible binding of some chemicals. It can also prevent the enteral absorption and enhance elimination of drugs administered for therapeutic purposes. Aspiration of activated charcoal along with gastric contents can result in large and small airway obstruction, pneumonitis, and death [56,57].

Although there are no absolute contraindications, activated charcoal is not recommended for ingestions of acids, alkali, and hydrocarbons that are poorly absorbed and have low systemic toxicity (low-viscosity petroleum distillates and turpentine) [47,48,54]. It does not adsorb these corrosives and obscures endoscopic assessment of the extent of injury. With hydrocarbons, it may promote vomiting and increase the risk of pulmonary aspiration.

**Gastric Lavage.** Gastric lavage can directly remove ingested chemicals from the stomach and thereby prevent their absorption [45]. As with activated charcoal, the efficacy of gastric lavage decreases as the time between ingestion and treatment increases. In animal studies and in simulated overdoses in human volunteers, gastric lavage decreased chemical absorption an average of 42% (range 29% to 90%) when performed within 20 minutes of chemical administration, 26% (13% to 38%) when performed at 30 minutes, and 17% (8% to 32%) when performed at 60 minutes [45]. Efficacy is enhanced if activated charcoal is given before and after lavage, but not if it is only given afterward [43].

Gastric lavage is performed by first aspirating stomach contents and then repetitively instilling and withdrawing fluid through a large orogastric tube. It appears to be most effective if the patient is placed in a left lateral decubitus Trendelenburg position. The left lateral decubitus position has also been shown to delay spontaneous drug absorption [58].

The simplest, quickest, and least expensive method to use is a funnel connected to the lavage tube, raising it 2 to 3 feet above the level of the stomach when administering fluid and lowering it 2 to 3 feet below the stomach to allow drainage [59]. Tap water is the lavage fluid of choice for patients older than 2 years. The optimal volume of fluid for each lavage cycle is unclear. Recommended amounts range from 60 to 800 mL for adults and up to 10 mL per kg of body weight for children [45]. Larger aliquots (5 to 10 mL per kg body weight) are superior to smaller ones. It is recommended that lavage be continued until the return is relatively clear.

Although endotracheal intubation does not completely prevent aspiration during gastric lavage, it is recommended to reduce the risk of aspiration, facilitate other investigations and for the patient’s predicted clinical course [45].

As in experimental studies, the clinical efficacy of gastric lavage
decreases as the time between overdose and initiation of treatment increases. The efficacy of gastric lavage increases in cases of toxin induced gastroparesis or decreased intestinal motility.

Although there are no absolute contraindications to gastric lavage, its use for corrosive and hydrocarbon ingestions is not recommended [45,57]. With corrosives, insertion of a tube may increase the risk of esophageal perforation. Gastric lavage should be reserved for large ingestions of liquid acid or alkali and for agents that can cause systemic toxicity (heavy metals, hydrazine), and only if it can be performed within 1 to 2 hours of exposure. Because lavage may increase the risk of pulmonary aspiration after hydrocarbon ingestion, it should only be considered for large ingestions of agents that have systemic toxicity (camphor, halogenated and aromatic derivatives, and those that contain heavy metals or pesticides) and in conjunction with the advice of a poison center.

Syrup of Ipecac. Although syrup of ipecac is simple to use, and was once widely available for home administration, it is less effective than activated charcoal in preventing chemical absorption in experimental studies and has more contraindications [42]. Vomiting exposes patients to aspiration risks and may preclude the administration of activated charcoal or other oral antidotes. There is virtually no role for Ipecac in the critically ill poisoned patient.

Whole-Bowel Irrigation. Whole-bowel irrigation refers to the enteral administration of large volumes of an electrolyte solution. It is commonly used to cleanse the GI tract before colonoscopy, barium enema radiography, and bowel surgery and can prevent the absorption of ingested chemicals by increasing gut motility [46,60].

In experimental studies, whole-bowel irrigation decreased chemical absorption by about 70% (range, 67% to 73%) when initiated 1 hour after simulated overdose of ampicillin, paraquat, and sustained-release formulations of aspirin and lithium and 4 hours after a supratherapeutic dose of enteric-coated aspirin [60–62]. Whole-bowel irrigation solutions have been found both to enhance [63,64] and to interfere [60,62] with the in vitro adsorptive capacity of activated charcoal.

Whole-bowel irrigation is performed by administering a solution of electrolytes and polyethylene glycol by nasogastric tube at a rate of 0.5 L per hour in children 9 months to 6 years of age, 1 L per hour for 6- to 12-year-olds, and 2 L per hour for those older than 12 years, until the rectal effluent is clear, which typically takes 2 to 4 hours.

In human volunteer studies, whole-bowel irrigation was more effective than gastric lavage [60,65]. The combination of charcoal followed by whole-bowel irrigation was more effective than whole-bowel irrigation
alone [61,62]. Although no controlled studies addressing efficacy in overdose patients have been performed, it may be useful for ingestions of enteric-coated or sustained-release pharmaceuticals, foreign bodies (bezoars, button batteries, drug packets, and lead paint chips), and agents that are poorly adsorbed by activated charcoal (iron and other metals), and for patients with extremely large ingestions or delayed presentations [47,64–70]. Potential complications of whole-bowel irrigation include regurgitation and aspiration of gastric contents and abdominal distension with cramping [47,61]. Whole-bowel irrigation does not cause fluid and/or electrolyte abnormalities. Disadvantages of whole-bowel irrigation are that it is unpleasant, labor intensive, and time-consuming. Contraindications include bowel obstruction, perforation or ileus, and hemodynamic instability. It can be safely performed in intubated obtunded patients.

**Endoscopy and Surgery.** Gastric endoscopy, using baskets or snares to grasp or break up particulate chemicals, can be used to remove foreign bodies (button batteries that break apart or fail to pass beyond the pylorus) and gastric pill bezoars (see “Absorption” section). It should be reserved for patients with severe or potentially lethal poisoning, such as those with large amounts of heavy metal visible in the stomach on radiograph and those who continue to deteriorate and have rising drug levels despite attempts at GI decontamination by other methods. Endoscopy should never be used for the removal of drug packets, because it may cause rupture and lethal toxicity.

Immediate retrieval by laparotomy is indicated for patients who develop toxicity after the ingestion of packets containing cocaine. Surgery should also be considered when endoscopic removal is unsuccessful or impossible because of the location of the toxin or foreign body [71].

**Cathartics.** Cathartics are osmotically active saccharides (mannitol, sorbitol) or salts (magnesium citrate, magnesium sulfate, and disodium phosphate) that cause retention of fluids within the gut, thereby stimulating GI motility and the evacuation of intestinal contents [44,72]. In animal and human volunteer studies, cathartics have variable but clinically insignificant effects on chemical absorption [44]. Their effect on the efficacy of activated charcoal is also minimal and clinically insignificant [73,74]. There is currently no role for cathartics in the critically ill poisoned patient.
**Dilution.** The administration of water, milk, or other drinkable liquids is now recommended as a primary treatment only for corrosive ingestions. In this setting, dilution may lower the concentration of chemical and limit its toxicity. To be effective, dilution should be accomplished as soon as possible. The volume of fluid should not exceed 5 mL per kg, because larger amounts may induce vomiting and cause further esophageal exposure. Dilution is no longer recommended to prevent toxin absorption. It may facilitate the dissolution of solid chemicals, increase the amount of chemical in solution, and stimulate gastric emptying, thereby enhancing chemical absorption.

**Antidotal Therapy**

Antidotes directly or indirectly counteract the effects of toxins [10,11]. They can be classified as *selective* or *nonselective*. Selective antidotes act by competing with chemicals for target sites or metabolic pathways, by binding and neutralizing them, by promoting their metabolic detoxification, and by antagonizing their autonomic effects via activation or inhibition of opposing neuronal pathways (see Table 97.11). Nonselective antidotes act by correcting metabolic derangements or enhancing nonmetabolic toxin elimination.

Although antidotes can reduce morbidity and mortality, few are available and most are potentially harmful. Reasonable diagnostic certainty is necessary for their safe and effective use. Specific indications, contraindications, dosing, and potential complications are discussed in the following chapters. A summary Table of antidotes can be found in the Appendix.

Enhancement of Elimination

The nonmetabolic elimination of most toxins can be accelerated by therapeutic interventions such as diuresis, urine alkalization, GI dialysis (i.e., multiple-dose activated charcoal or whole-bowel irrigation), and extracorporeal techniques.

All enhanced elimination procedures are associated with potential complications, and some require specialized equipment and expertise. Reasonable diagnostic certainty is generally a prerequisite to their use. In general, invasive elimination procedures should be reserved for patients with severe poisoning and/or those who deteriorate or fail to improve despite aggressive supportive care, antidotal therapy, and noninvasive methods of toxin removal.

Diuresis and Manipulation of Urinary pH
Maintenance of a dilute urine flow enhances toxin excretion by decreasing the passive distal tubular reabsorption of toxins that have undergone glomerular filtration and proximal tubular secretion [9–11]. Increasing urinary pH (considered neutral at a pH of 6) can enhance the renal excretion of acidic toxins by a mechanism known as ion trapping. Like all membranes, those of the nephron, particularly the distal tubule, are generally more permeable to nonionized and nonpolar molecules than to ionized and polar ones. After filtration and secretion, nonionized forms of weak acids become ionized and trapped in an alkaline urine. Diuresis and urinary alkalization act synergistically [75].

Diuresis alone can enhance the renal excretion of alcohols, bromide, calcium, fluoride, lithium, meprobamate, potassium, and isoniazid. Except for calcium and potassium, however, clinical efficacy remains unproven.

Alkalization of the urine can enhance the excretion of the chlorophenoxy acetic acid herbicide 2,4-D (and probably 2,4,5-T), chlorpropamide, diflunisal, fluoride, methotrexate, phenobarbital (and probably other long-acting barbiturates), sulfonamides, and salicylates. Only for phenobarbital and salicylate poisoning is urinary alkalization accepted as clinically effective [76].

The goal of urinary alkalization is a urine pH of 7.5 or greater. An alkaline diuresis solution can be prepared by adding three ampules (132 mEq) of sodium bicarbonate to dextrose 5% in water such that the final solution is nearly isotonic. Fluids are administered at roughly the same rate as the desired urine output. Acetazolamide should not be used to produce an alkaline urine because it may worsen toxicity by causing a concomitant systemic acidosis, resulting in an increase in the amount of unionized drug in the blood and enhanced tissue distribution. It may also compete with acidic drugs for tubular secretion and thereby inhibit their elimination. Systemic hypokalemia will prevent effective urine alkalization by retention of potassium and excretion of hydrogen ions into the urine at the level of the hydrogen potassium ATPase.

Acid–base status, fluid balance, electrolyte parameters, and clinical response must be carefully monitored during therapy. Urine pH should be measured hourly.

**Multiple-Dose Activated Charcoal**

Repetitive activated charcoal administration can enhance the elimination of previously absorbed chemicals by binding them within the GI tract as they are excreted in the bile, secreted by cells of the stomach or intestine, or passively diffuse into the lumen of the gut [55,77–79]. The charcoal–chemical complex is then excreted with stool. Multidose activated charcoal works by reverse absorption, using the entire surface of the gut
acting as a dialysis membrane. Activated charcoal keeps the concentration of free toxin in gut fluids near zero, and chemicals diffuse from blood perfusing the gut into luminal fluids as a result of concentration gradients. Interruption of enterohepatic or enteroenteric recirculation appears to be the underlying mechanism of action for a minority of toxins. Theoretically, multiple-dose charcoal can enhance the elimination of any chemical whose absorption is decreased by a single dose. Efficacy is predicted to be greatest for chemicals with a high charcoal binding capacity, physical, and pharmacokinetic characteristics that make them amenable to removal by extracorporeal methods (see later), and a long intrinsic elimination half-life (amiodarone, isotretinoin, organochlorine pesticides, and organometallic compounds) [80].

Multiple-dose activated charcoal enhances the elimination of most chemicals regardless of whether the chemical is administered orally or parenterally [79]. As with most forms of decontamination, the clinical efficacy of this therapy is difficult to prove. Although clinically significant reductions in half-life have been noted in patients with carbamazepine, dapsone, phenobarbital, quinine, and theophylline overdose, there are no prospective studies showing that this therapy reduces morbidity or mortality [79].

The efficacy of multiple-dose activated charcoal increases as the cumulative amount of charcoal administered increases. When the cumulative amount of charcoal remains constant, there is no difference in the efficacy of different dosing regimens (25 g every 2 hours vs. 50 g every 4 hours) [81]. With normal bowel activity, doses of activated charcoal of 0.5 to 1.0 g per kg every 4 hours are generally well tolerated. In those with decreased GI motility, smaller doses or less frequent intervals should be used. Alternatively, charcoal can be given by a slow, continuous nasogastric infusion. This method of administration may also be better for patients who cannot retain charcoal because of vomiting. Metoclopramide and ondansetron (or other serotonergic antiemetics) can also be given to control or prevent vomiting. Gastric aspiration should be performed before repeating the dose of charcoal.

Complications of multiple-dose activated charcoal are similar to those for charcoal used for GI decontamination. In addition, intestinal obstruction, pseudo-obstruction, and nonocclusive intestinal infarction have been reported in patients with decreased bowel motility treated with multiple doses of activated charcoal [82,83].

**Extracorporeal Methods**

Peritoneal dialysis, hemodialysis, hemoperfusion, hemofiltration, plasmapheresis, and exchange transfusion are theoretically capable of removing any chemical from the blood [81]. Most toxins undergo
significant tissue distribution, and few remain in the blood in amounts high enough to warrant extracorporeal removal. Hemodialysis is therefore most effective for toxins with volumes of distribution less than 1 L per kg. In addition, with dialysis techniques, only toxins that are small (molecular weight less than 500 to 1,500 Da), water soluble, and not highly bound to serum proteins (90% to 95% or less) readily diffuse across dialysis membranes. (Table 97.12) There remains very little evidence regarding the efficacy of continuous renal replacement therapy (CRRT) in the management of human poisonings. Even at high flow rates, CRRT’s ability to clear toxins is a fraction of that of traditional intermittent hemodialysis (IHD).

</table>

The clearance of a toxin by extracorporeal removal must be significantly greater than its intrinsic total body clearance (the sum of metabolic, renal, and other routes of clearance) to be considered effective from a pharmacokinetic perspective. As with other treatments, renal replacement therapy’s efficacy (ability to decrease morbidity and mortality) is based on observation, experience, and retrospective comparisons rather than on controlled prospective studies.

Hemodialysis is considered effective for the treatment of barbiturate, bromide, chloral hydrate, ethanol, ethylene glycol, isopropyl alcohol, lithium, methanol, procainamide, acetaminophen, theophylline, and salicylate poisoning. Because hemodialysis can remove toxins from the blood faster than they can redistribute from tissue to blood, a rebound increase in blood concentration and clinical relapse may occur within 1 or 2 hours of treatment.

Other techniques are less effective than hemodialysis. Peritoneal dialysis may be useful when these methods are not available or technically difficult (in neonates) or when anticoagulation may be
hazardous. Complications include infection, injury to intra-abdominal organs, and hypothermia. Plasma exchange may also be a useful alternative in neonates. It is effective for treating hemolysis (arsine poisoning) and methemoglobinemia. Two blood-volume exchanges are usually performed using central or peripheral arteriovenous or venovenous access. Complications include transfusion reactions and hypothermia.

Safe Disposition

ICU admission is recommended for patients with coma, refractory hemodynamic instability, respiratory depression, seizures, and/or dysrhythmias. Patients with extremes of temperature, severe agitation, or life-threatening metabolic abnormalities also benefit from intensive care. Patients who are less ill, stable, or even asymptomatic are frequently unnecessarily admitted to the ICU because of physician uncertainty, fear of late deterioration and potential litigation, and lack of an alternative monitored setting. Some patients may require close observation and cardiac monitoring; but unless active interventions are likely to be necessary, admission to an intermediate care unit, telemetry unit, or emergency department observation unit is appropriate. Length of hospital stay for patients with self-poisoning can be reduced by use of a multidisciplinary team that involves a toxicologist and psychiatrist as well as medical personnel [84].

Prevention of Recurrence

Suicidal patients require psychiatric assessment. If they are given prescriptions, the amount of drug (1 to 2 week supply) and number of refills should be limited. Substance abusers should be counseled regarding attendant medical risks and given the opportunity for rehabilitation through referral for behavior modification, supervised withdrawal, and abstinence or maintenance therapy.

Adults with accidental poisoning should be educated regarding the safe use of drugs and other chemicals. Assistance with the administration of medications may be required for visually impaired, elderly, developmentally delayed, or confused patients. Preventive education may be indicated for health care providers who have committed dosing errors or who are unaware of adverse drug interactions. When poisoning results from environmental or workplace exposure, the appropriate governmental agency (Environmental Protection Agency, Occupational Safety and Health Administration, National Institute of Occupational Safety and Health, or local state, or federal health departments) should be notified. Unsafe working conditions should be brought to the attention of employers. Industrial hygiene and occupational health services should
be offered if available. Finally, physicians have a duty to warn the general public (via press releases) of acute environmental hazards.
REFERENCES

Acetaminophen (N-acetyl-para-aminophenol [APAP]) is a nonopiate analgesic with excellent antipyretic activity but few anti-inflammatory effects. It belongs to the same drug family as phenacetin and acetanilid, the coal tar or aminobenzene analgesics [1,2]. Although APAP is the active metabolite of phenacetin, unlike phenacetin, it rarely, causes nephrotoxicity and does not cause methemoglobinemia or hemolytic anemia. Unlike aspirin, APAP has no barrier-breaker effect on the gastrointestinal tract and no effect on platelet function, has a high therapeutic index, and has not been implicated as a factor in Reye’s syndrome. As a result, APAP is the preferred agent for the treatment of fever and mild to moderate pain when anti-inflammatory and antiplatelet action is not important.

Acetaminophen is an active ingredient in several hundred products, including pure APAP formulations, combinations with opioid analgesics, and numerous combination cough and cold preparations. It is also available in an extended-release (ER) formulation (which contains 325 mg of immediate-release and 325 mg of delayed-release acetaminophen per tablet) as a suppository, and a recently available intravenous formulation.

Acetaminophen has a pKₐ of 9.5 and is quickly and almost completely absorbed after ingestion of therapeutic doses of immediate-release formulations (10 to 15 mg per kg every 4 hours), yielding peak plasma concentrations between 5 and 20 μg per mL within 30 to 120 minutes. Clinical effects are noted within 30 minutes. Liquid preparations are absorbed slightly faster than solid formulations. Rectal absorption is similar to that of oral ingestion. The volume of distribution of APAP is 0.9 to 1.0 L per kg, and protein binding is negligible. Therapeutic plasma concentrations range from 10 to 20 μg per L, and elimination after
therapeutic dosing follows first-order kinetics, with an average half-life of 2 to 4 hours [1]. Elimination is slower in neonates and young infants [3], the elderly [2], and in patients with hepatic dysfunction [4]. Clinical effects persist for 3 to 4 hours after therapeutic doses.

After overdose, peak acetaminophen levels are usually noted within 4 hours. The ingestion of very large doses and the concomitant ingestion of agents that delay gastric emptying (e.g., anticholinergics and opioids) may result in peak levels occurring later. Prolonged absorption with a late rise in the acetaminophen level has also been reported after an ER overdose [5].
The short- or long-term therapeutic use of APAP is rarely associated with adverse effects. Hypersensitivity reactions, such as urticaria, fixed drug eruption, angioedema, laryngeal edema, and anaphylaxis, are extremely rare [6]. Although high-dose APAP has been associated with chronic renal impairment [7], a cause–effect relationship has not been established.

Despite remarkable safety in appropriate doses, APAP can cause fatal hepatic necrosis after overdosage. This was first recognized in Europe more than 50 years ago, and the first cases of hepatotoxicity in the United States were reported in 1975. Since that time, the incidence of APAP poisoning has increased dramatically in parallel with its increased availability and use; APAP is now the most common drug involved in exposures reported to US poison control centers, accounting for more than 141,000 calls in 2015 [8]. The incidence of occult poisoning is unknown, but based on retrospective data approximately 1 of every 70 overdose patients may have a detectable acetaminophen concentration and approximately 1 in 300 a potentially toxic APAP ingestion [9].

The metabolism of APAP explains its toxicity and the rationale for the current treatment of overdose (Fig. 98.1) [2]. After therapeutic doses, approximately 90% of APAP metabolism occurs by hepatic conjugation with sulfate or glucuronide to form inactive, nontoxic, renally eliminated metabolites. In adults, glucuronidation is the predominant route; in infants and young children, sulfation is the major pathway. Less than 5% of APAP is eliminated unchanged in the urine. The small remaining fraction (approximately 5%) undergoes oxidation by the P450 mixed-function oxidase enzyme system (CYP2E1) to yield the highly reactive, potentially toxic, electrophilic intermediate N-acetyl-para-benzoquinoneimine (NAPQI) [10]. NAPQI is quickly detoxified by reduced glutathione (GSH) to form nontoxic cysteine and mercapturic acid conjugates that are excreted in the urine.
After overdose, the amount of drug metabolized by the P450 route increases, because of a greater total drug burden and saturation of alternative enzymatic pathways [11]. As a result, GSH utilization increases. If GSH regeneration is inadequate to meet demand and becomes significantly depleted, NAPQI can persist and react with hepatocyte macromolecules, resulting in the death of hepatocytes. In
animal studies, such injury occurs when GSH stores reach less than 30% of normal [12]. Hepatocyte necrosis is most pronounced in areas of highest CYP2E1 activity: the centrilobular (central venule) zones of the liver. The degree of injury can range from asymptomatic elevations in aminotransferase levels to fulminant liver failure. Although far less common, the same process can occur in the kidney [13]. Very rarely, renal toxicity can occur in the absence of serious hepatotoxicity [14].

Pancreatitis can occur, and diffuse myocardial necrosis has been noted in fatal cases. Very rarely, with massive ingestions, early coma and metabolic acidosis may be seen [15]. Although uncommon, thrombocytopenia after acute overdose has also been described [16]. The mechanisms causing these atypical toxicities are unknown, and it is unclear to what extent these effects are directly due to APAP.

The precise dosage required to produce hepatotoxicity is unknown and almost certainly varies to some degree with individual differences in CYP2E1 activity, GSH stores, and capacity for GSH regeneration. Retrospective data suggest that significant toxicity is likely only after acute overdoses of greater than 250 mg per kg in adults [13], and prospective studies have suggested that toxicity is unlikely in unintentional pediatric ingestions of up to 200 mg per kg [17]. The possibility of toxicity at lower doses and skepticism regarding the accuracy of overdose histories have led to acceptance of a more conservative definition of risk, particularly in the United States. On the basis of APAP’s volume of distribution and the well-established accuracy of APAP blood levels in predicting toxicity (see later), it is currently recommended that single ingestions of greater than 140 to 150 mg per kg be considered potentially toxic.

Elevated aminotransferase concentrations have also been reported after repeated ingestions of therapeutic or slightly greater doses of APAP [18]. Individuals who have conditions associated with increased CYP2E1 activity (e.g., chronic alcoholics) or glutathione depletion such as children younger than 10 years of age [19], those with chronic malnutrition, recent fasting (due to intercurrent illness), or recent ethanol use [20] may be at increased risk for such toxicity, but the accuracy of these reports has been challenged, and their therapeutic implications remain controversial. Such individuals are likely to have low hepatic carbohydrate and sulfate stores and, hence, decreased capacity for APAP metabolism via the glucuronidation and sulfation. There is currently no valid estimation of the amount, frequency, or duration of the dosing that defines risk. It appears that after repeated doses, accumulation of APAP to concentrations associated with toxicity after acute overdose is not required and that sustained moderate elevations are sufficient to cause GSH depletion and toxicity [21]. Such observations suggest that the APAP level at which NAPQI production exceeds GSH regeneration is near, or
possibly within, the therapeutic range and that GSH stores and the capacity for its regeneration are the most important factors in the development of hepatotoxicity. They also support the concept that hepatotoxicity is more dependent on the area under the curve (time vs. concentration) of APAP than the peak drug level.

**TABLE 98.1 Treatment of Acetaminophen Poisoning or Associated Hepatotoxicity**

1. Administer activated charcoal if ingestion within 1–2 h
2. Administer NAC either IV (preferred) or orally
3. Early consultation with hepatology and or transplant services for critically ill patients
4. Psychiatric evaluation for all intentional overdoses

Intentional acute overdose is the most common cause of toxicity and fatalities, but accidental therapeutic overdosing and the abuse of opioids with unintentional coingestion of APAP (e.g., with codeine or propoxyphene) have also been reported. Therapeutic overdoses may result from dosing calculation errors, excessive self-treatment, the use of adult formulations or extrastrength formulations when lower dosage formulations were intended, and errors involving substitution of higher dose rectal suppositories for similar-appearing lower dosage forms.

The importance of accurately diagnosing APAP toxicity soon after overdose extends beyond the high frequency with which it is encountered and its potential for causing morbidity and mortality. Acetaminophen is unique among common toxic exposures because effective treatment requires recognition of potential poisoning and initiation of therapy when no reliable clinical signs of overdose are present. Physicians must therefore consider occult APAP ingestion and liberally obtain APAP levels on all overdose patients to avoid missing the diagnosis.
Acetaminophen hepatotoxicity can be divided into four clinical stages based on the time interval after ingestion: stage I (0 to 24 hours), the latent period; stage II (24 to 48 hours), the onset of hepatotoxicity; stage III (72 to 96 hours), maximal hepatic injury; and stage IV (4 days to 2 weeks), recovery [2,13].

During stage I, patients may be completely asymptomatic but often experience nausea, vomiting, and malaise, which may be accompanied by pallor and mild diaphoresis. There is no known correlation between presence or absence of early symptoms and the risk of hepatotoxicity. Although late in stage I very sensitive indicators of hepatic injury, such as γ-glutamyltransferase level, may be elevated, more widely used laboratory studies (e.g., aspartate aminotransferase [AST], alanine aminotransferase, prothrombin time, bilirubin) are completely normal. Early coma and metabolic acidosis have been reported in patients with massive ingestions [15], but these findings are so atypical that other causes should be suspected. They should be attributed to APAP only if the APAP concentration is extremely high and other etiologies have been excluded.

Symptoms during stage II are typical of hepatitis and include right upper-quadrant abdominal pain, nausea, fatigue, and malaise. Physical examination often reveals right upper-quadrant tenderness and hepatomegaly. The first elevation of aminotransferase levels usually occurs between 24 and 36 hours after APAP ingestion, but in the most severe cases, it can occur by 16 hours or earlier. Early in stage II, tests reflecting liver function, such as bilirubin and prothrombin time, are most often normal or only slightly elevated. Marked elevations of aminotransferase levels (greater than 1,000 IU per L) within 24 hours or of bilirubin and prothrombin time within 36 hours should suggest that the time of ingestion was earlier than reported. Although unusual, in severe cases, marked liver function abnormalities may be evident by 36 to 48 hours. Complications during stage II are directly related to the degree of liver injury and may include coagulopathy, encephalopathy, acidosis, and hypoglycemia. With few exceptions, life-threatening problems are not seen earlier than 48 hours, and death in this period is distinctly rare. Renal dysfunction, manifested by rising creatinine and an active urinary sediment, may become evident during this stage but usually lags somewhat behind the hepatic injury. The blood urea nitrogen may also be elevated, but it can be normal in the presence of hepatic failure and resultant decreased urea formation.

Biochemical evidence of liver injury becomes most pronounced during
stage III. With successful treatment, however, peak aminotransferase levels may sometimes occur earlier (Fig. 98.2). Most patients, even those with markedly elevated aminotransferase levels, go on to recover fully. Most deaths occur 3 to 7 days after ingestion and result from intractable metabolic disturbances, secondary complications such as cerebral edema or dysrhythmias, or exsanguination due to coagulopathy. Renal failure may result from acute tubular necrosis. Some degree of renal dysfunction occurs in approximately 25% of patients with significant hepatotoxicity [15]. Even when severe, renal failure is almost always reversible.

**FIGURE 98.2** Expected time course of aminotransferase elevation due to acetaminophen-induced hepatotoxicity. The solid line represents typical course; the dashed line represents course of severe toxicity. ALT, alanine aminotransferase; AST, aspartate aminotransferase.

(Adapted from Jaeschke H, Mitchell JR: Neutrophil accumulation exacerbates acetaminophen-induced liver injury [abstract]. FASEB J 3:A920, 1989, with permission.)

During stage IV, if sufficient hepatocytes remain viable and the patient survives, the liver regenerates. Recovery is often complete by day 5 or 6 in patients with minimal toxicity, but those with more serious poisoning may not be clinically normal for 2 weeks or more. It is interesting that even patients with severe toxicity who survive regain normal liver function. There are no known cases of chronic or persistent liver abnormalities from APAP poisoning. In those who ultimately die, a slow decline in aminotransferase levels without clinical improvement may be seen. Declining enzyme levels merely represent a washout of those released at the time of the initial insult, not a recovery of normal liver
function. These patients can be identified by persistent or increasing marked elevations of bilirubin and prothrombin time. Although this pattern is occasionally seen in patients who recover, most survivors do not have significant or persistent bilirubin or prothrombin time elevation after aminotransferase levels fall.

Because of variations in dosing patterns and patient characteristics, the time course of toxicity in patients with repeated ingestions is not well defined. With chronic toxicity, dose–response patterns differ from those of acute overdose, but the clinical manifestations are the same.
DIAGNOSTIC EVALUATION

The diagnostic evaluation consists of determining the risk of toxicity and assessing for it. The serum APAP concentration is used to predict toxicity after acute overdose. If the APAP concentration between 4 and 24 hours after ingestion falls on or above the acetaminophen treatment nomogram line (Fig. 98.3), the patient should be considered at risk for hepatotoxicity, and hence in need of antidotal therapy (see later). Conversely, if the APAP concentration is even slightly below the nomogram line, the risk of hepatotoxicity is negligible and antidotal therapy is not necessary. The original Rumack–Matthew nomogram line, which defined the risk of toxicity based on the natural course of untreated patients [22], was actually 25% higher than the line now used in the United States. Hence, the nomogram has a 25% safety margin that allows one to be rigid when using the nomogram to make treatment decisions.

FIGURE 98.3 Acetaminophen treatment
nomogram. Patients with acetaminophen concentrations on or above the line require treatment with N-acetylcysteine.

(Adapted from Jaeschke H, Mitchell JR: Neutrophil accumulation exacerbates acetaminophen-induced liver injury [abstract]. FASEB J 3:A920, 1989, with permission.)

There are, however, some important caveats regarding use of the nomogram. First and foremost, it applies only to single acute ingestions. Second, when there is uncertainty about the exact time of ingestion, the worst-case scenario should be assumed. For example, if the ingestion was between 4 and 6 hours earlier, the 6-hour value on the nomogram should be used. And finally, when levels are obtained 20 to 24 hours after overdose, the limit of detection of the APAP assay must also be considered. Because most hospitals use immunoassays with a detection limit of 10 μg per mL, potentially toxic APAP levels during this period will be below this limit and reported as nondetectable, which does not necessarily mean nontoxic. Again, a worst-case scenario should be assumed, and antidotal treatment should be given until the level is confirmed to be nontoxic by a more sensitive assay, or until it has been determined that the patient is asymptomatic and has no laboratory evidence of hepatotoxicity.

With rare exceptions (see later), a single APAP concentration within the time specified by the nomogram is sufficient to plan appropriate therapy. Although it is true that the elimination half-life of APAP is related to the likelihood of toxicity, half-lives should not be relied on in making therapeutic decisions. The observations that half-lives greater than 4 hours were associated with toxicity and that toxicity was negligible if APAP half-life was less than 4 hours [23] were based on multiple APAP determinations in untreated patients over a 36-hour period. Because treatment must be started as early as possible [24] and treatment may alter APAP elimination [11], half-life determinations are not relevant to current standards of care.

There are three situations in which repeat measurements may be of value. The first is in the patient with a time of ingestion that is unknown, but that was within 4 hours. In this situation, an increasing APAP level indicates ongoing absorption from a recent ingestion. To detect a rising level and define the peak value, repeat determinations must be frequent (every hour) until the level declines. This prevents underestimation of the peak value due to incomplete absorption at the time of the first level. It also may rule out toxicity by detecting a peak value less than 150 μg per mL.

The second situation in which repeating the APAP may be useful is after an overdose of an ER formula. Because of prolonged absorption, patients with nontoxic APAP levels soon after ingestion may have
subsequent concentrations that are toxic by the nomogram [25]. The optimal time to repeat drug levels to detect such nomogram line-crossers is unknown. In one patient, a potentially toxic APAP level did not occur until 14 hours after ingestion [5]. The manufacturer recommends obtaining a second APAP level 4 to 6 hours after the initial one [26]. Others have recommended that to avoid missing a potentially toxic level, drug levels should be measured every 2 hours from 4 to 16 hours after overdose [27].

Finally, repeat APAP levels may be of value in the patient with very high levels and slow elimination in whom it is possible that APAP may still be present at the completion of therapy. Antidotal treatment should not be discontinued while APAP is still present. This is particularly relevant as shorter courses of antidotal therapy have become the routine.

In assessing the patient who is found to be at risk for toxicity and hence requires hospitalization and antidotal treatment, a complete blood count, electrolytes, blood urea nitrogen, creatinine, glucose, prothrombin time, aminotransferase levels, and bilirubin should be obtained at admission and repeated every 24 hours until resolution of toxicity is noted. If liver failure develops, laboratory values, particularly prothrombin time and glucose, must be obtained more frequently. Renal function, acid–base status, amylase, and electrocardiogram may also need to be evaluated or repeated. Assessment of renal, pancreatic, and myocardial toxicity should follow the same guidelines as those for other etiologies.
MANAGEMENT

Treatment includes gastrointestinal decontamination, antidotal treatment (if indicated), and support of organ function. Unless clinically significant hepatic or renal failure develops, management consists only of antidote administration and monitoring of signs, symptoms, and laboratory parameters. Although this can be accomplished outside the intensive care unit, patients often require monitoring or treatment for toxicity owing to coingestions or constant observation because of suicide risk. If significant hepatic failure ensues, intensive care unit admission is required for close monitoring and treatment of complications. Invasive monitoring is infrequently required, but may be useful if multisystem failure occurs.

Gastrointestinal Decontamination

Gastrointestinal decontamination is recommended for patients who can be treated within 1 to 2 hours of APAP overdose. Although once considered controversial and even contraindicated, activated charcoal is now considered the method of choice for gastrointestinal decontamination. As routine treatment of APAP poisoning has moved from oral N-acetylcysteine (NAC) to intravenous administration, this formerly contentious point has been rendered moot.

Antidotal Treatment

The observation that hepatotoxicity occurs only when GSH is depleted led to a search for agents that might increase available sulfhydryl groups either by increasing GSH or by providing alternative sulfhydryl sources. Exogenous GSH does not readily enter cells, so various precursors and substitutes, including cysteamine, methionine, and NAC [24,28], have been tried. Although all regimens are effective when started within 8 to 10 hours of ingestion, cysteamine was abandoned because of its toxicity, and methionine has been replaced by NAC, which is more effective and probably carries less risk of worsening hepatic encephalopathy when liver failure is present.

There are several suggested mechanisms of action of NAC. In cells, NAC is converted to cysteine, a GSH precursor, and thus increases GSH stores. Second, NAC or cysteine can substitute directly for GSH because it
has available sulfhydryl groups. Third, NAC augments the sulfation of APAP to nontoxic metabolite by providing sulfur substrate [11]. Fourth, NAC may promote the back conversion of NAPQI to its precursors, although this has not been demonstrated in humans. Finally, there is accumulating evidence that NAC may be beneficial, even after liver injury has occurred, through mechanisms other than its effects on APAP metabolism [29]. Suggested mechanisms for these late effects of NAC include direct antioxidant action to modify postinflammatory radical-mediated destruction, restoration of enzyme function in injured tissue, and correction of microvascular function by restoring endothelial-derived relaxing factor [29]. It is likely that the relative importance of each of the previously described effects of NAC in any given patient varies with the severity of the overdose and the delay to NAC initiation. These variations may explain apparent differences in efficacy between different NAC protocols.

Two treatment regimens are currently approved for use in the United States. The first consists of a 72-hour course of oral NAC given as a 140-mg-per-kg loading dose, followed by 17 doses of 70 mg per kg every 4 hours beginning 4 hours after the loading dose, for a total NAC dose of 1,330 mg per kg [30]. The second regimen consists of an intravenous loading dose of acetylcysteine of 150 mg per kg in 200 mL dextrose 5% in water (D5W) over 15 minutes, followed by 50 mg per kg in 500 mL D5W over 4 hours, then 100 mg per kg in 1 L D5W over the next 16 hours [31]. This is identical to the standard treatment regimens in Europe and Canada [28]. Because the FDA-approved dosing requires three separate intravenous formulations, some poison control centers, hospitals, and medical toxicologists have simplified NAC protocols that differ from the FDA-approved dosing [32].

For oral therapy, NAC is usually supplied as a 20% solution (20 g per 100 mL), which should be diluted 3 to 1 to yield a 5% mixture with juice or a soft drink to increase its palatability and decrease gastrointestinal side effects. Antiemetics are frequently required to treat antecedent vomiting or vomiting due to NAC. If antiemetics fail, NAC can be given by gastric or duodenal tube. Various other methods may prove helpful in decreasing emesis after dosing: chilling the solution with ice chips, using a straw and covering the container, diluting to a 10% solution, or administering the solution over 15 to 60 minutes instead of as a bolus. If vomiting occurs within 1 hour of any dose, that dose should be repeated.

The use of oral or IV NAC is dependent on the experience of the clinician, the local hospital formulary, severity of the patient, and physician preference. Most patients can be adequately treated with oral NAC if it is begun within 8 to 10 hours of ingestion. Other patients, particularly those who present after 8 to 10 hours or those with encephalopathy, should receive IV NAC therapy.
There are no well-documented serious side effects of oral NAC, although nausea and vomiting are extremely common [33]. Side effects from intravenous NAC are far less common but potentially more serious. There are several reports of serious or fatal anaphylactoid reactions (e.g., hypotension, bronchospasm, rash, death) to intravenous NAC during the 20-hour protocol, and minor dermatologic reactions are common [34,35]. It is important to recognize that adverse effects of intravenous NAC are not truly anaphylactic; they are dose and concentration dependent [34]. As a result, more dilute and slowly administered doses are better tolerated [36]. Except for an anaphylactoid reaction in one patient after an NAC overdose, there were no serious adverse reactions reported during the 48-hour intravenous protocol [36]. Transient skin rash occurred in approximately 15% of patients during the loading dose but did not necessitate discontinuing treatment. Even with more serious reactions, NAC therapy can often be continued or resumed after treatment with diphenhydramine [35].

All dosing protocols appear to be equivalent when NAC is started within 8 hours of ingestion. Efficacy decreases with longer delays in therapy, with apparent differences between the dosing regimens when NAC is started after 16 hours. With late treatment, 82% of high-risk patients treated with the 20-hour regimen developed aminotransferase values above 1,000 IU per L, an incidence not significantly different from the 89% incidence reported in untreated historical control subjects [28]. After treatment with 48 hours of intravenous NAC, only 58% of late-treated patients developed hepatotoxicity, a result that was significantly better than that with the 20-hour course or no treatment [36]. After 72 hours of oral NAC, only 41% of late-treated patients developed hepatotoxicity [24], although this was not statistically different from the 48-hour protocol [36]. These studies included only patients receiving NAC within 24 hours of ingestion.

In the first controlled study of NAC started more than 24 hours after overdose, intravenous NAC started after onset of liver failure (median 53 hours after APAP) reduced cerebral edema, need for vaso pressors, and mortality [37]. It is interesting that this study used the same NAC dosing that had earlier been found ineffective more than 15 hours after overdose [28], but instead of discontinuing NAC after 20 hours, therapy was continued until either recovery or death occurred.

The numerous actions of NAC may explain why various NAC protocols are equivalent when started early but not when started late. When started within 8 hours of overdose, NAC probably exclusively affects APAP metabolism and GSH turnover, and its role is preventative before GSH depletion and NAPQI covalent binding. In this setting, NAC may be needed only until APAP metabolism is complete; thus, shorter courses of NAC are effective. With further treatment delay, the role of NAC may
increasingly be to ameliorate the effects of NAPQI covalent binding, and by 16 hours after ingestion, this may be its sole action and would explain why longer courses of NAC, continued during the period of maximal liver injury, appear to be superior. These considerations have led to selective management, such as short-course NAC for those treated early who do not develop aminotransferase elevations or late treatment with NAC for any patient who develops liver injury (see later).

Cimetidine has been suggested as a possible antidote for APAP because of its inhibitory effect on P450 activity. Animal studies showed efficacy of high-dose cimetidine given before or soon after APAP, but there is no evidence of efficacy in humans [38]. Even if the massive dose suggested by animal studies proved to be safe and effective in humans, its theoretical effect would require early administration. In problematic cases, such as late presentation, there is no theoretical or experimental support for cimetidine use. Hence, although cimetidine is not contraindicated, it has no proven role and should never be considered an alternative to NAC.

Supportive Care

The management of hepatic failure, renal failure, or other end-organ manifestations of APAP toxicity should be treated according to usual guidelines. In view of the increased availability and success of liver transplantation, the most severely ill patients deserve this consideration. Several successful transplants have been done after APAP overdose. The greatest challenge is early identification of patients destined for irreversible hepatic failure (see the section Prognosis and Outcome).
SPECIAL CONSIDERATIONS

Acute Overdose in Alcoholics and Other High-Risk Patients

Certain subgroups of patients appear to be at greater or lesser risk for APAP toxicity, but this fact is of more theoretic than practical value in the management of acute overdose. Higher risk is expected in patients with increased CYP2E1 enzyme activity from chronic use of agents that induce this enzyme (e.g., ethanol, barbiturates, phenytoin, sedative–hypnotics, griseofulvin, haloperidol, tolbutamide) or decreased GSH stores or low GSH turnover rates (e.g., malnourished patients or those with liver disease). Lower toxicity might be expected when CYP2E1 activity is inhibited by chronic use of agents such as cimetidine or when a patient has coingested an agent that is metabolized by this enzyme, thus competing with APAP and decreasing NAPQI formation.

Acute overdose studies in animals demonstrated increased toxicity after chronic ethanol use and decreased toxicity when ethanol and APAP were coingested. The protective effect of ethanol coingestion appears to be due to competitive inhibition of NAPQI formation by P450 ethanol metabolism. Chronic ethanol use, particularly in an alcoholic that is currently abstinent could worsen toxicity by causing P450 induction, GSH depletion, or some other unknown mechanism. For example, an alcoholic might be protected by the acute coingestion of ethanol or be nutritionally deprived and have lower P450 activity. Despite suggestions that some of these factors may be important, the amount of chronic ethanol or drug use that is clinically significant is unknown and certain to be variable.

Because the treatment nomogram line is conservative, treatment decisions after acute overdose should be made in the same manner as described previously, regardless of chronic coingestants.

Acute Overdose in Pediatric Patients

Of 417 children with acute APAP overdose, 49 of whom had plasma APAP levels over the nomogram line, indicating potential toxicity, only three (6.1%) developed an AST or ALT greater than 1,000 IU per L. This incidence is less than that reported in adults, leading to speculation that children are relatively protected from APAP toxicity.

Several pharmacokinetic differences between children and adults have been noted. The most consistent finding is that the ratio of APAP-sulfate to APAP-glucuronide is higher in children than in adults, but this
difference in nontoxic routes of metabolism has not been shown to be associated with a decrease in production of NAPQI. Thus, increased sulfation has not been proven favorably to alter NAPQI formation. Decreased P450 activity, and thus decreased NAPQI formation, has also been postulated in children, but decreased P450 activity is noted only in fetal and neonatal subjects [45]. Most APAP poisonings occur outside the newborn period, when P450 activity may be even greater than in adults. Hence, this theory cannot explain a hepatoprotective effect in older children. If children are actually less susceptible to APAP toxicity, it may be because of an increased ability to regenerate GSH, but this, too, is unproven.

Perhaps the most likely explanation is that pediatric overdoses are quantitatively less severe. In adults, particularly those treated late, the outcome is worse in patients with very high APAP levels [24]. Substantial toxicity has also developed in children with very high concentrations, but there are too few cases to allow for any conclusions. Until larger numbers of children with very high APAP levels are studied, patients of all ages with a significant overdose must still be considered at substantial risk and managed accordingly. As with adults, the longer the time between ingestion and presentation or treatment in children with potentially toxic drug levels, the greater the incidence of hepatotoxicity and the worse the prognosis [21].

Acute Overdose in Pregnancy

Although experience with overdose in pregnancy is limited [46], certain conclusions seem valid. First, there is clear evidence that APAP overdose can result in morbidity and mortality to women and the fetus at all stages of pregnancy. Second, there currently is no evidence that NAC is harmful to a pregnant woman or her fetus. Third, NAC is hepatoprotective to the women. Fourth, NAC crosses the human placenta [47], and this is likely to be beneficial to the fetus. On the basis of these observations, it is recommended that pregnant women be treated according to standard guidelines regardless of gestational age of the fetus and that newborns delivered during a course of maternal NAC treatment should also complete a course of NAC after delivery.

Acute Overdose of Extended-Release Acetaminophen

Because experience with ER APAP overdose is limited, the applicability of the nomogram, which was derived from clinical outcome data in patients with immediate-release APAP overdose, to those with ER APAP overdose remains to be determined [25–27]. Although it is agreed that patients who have a potentially toxic APAP level after acute acetaminophen ER overdose require NAC, the management of those with levels that are
elevated but nontoxic is controversial. Some have suggested that such patients do not require NAC [48]. Given that peak drug levels after supratherapeutic but nontoxic doses of ER acetaminophen are only two-thirds of those seen after equivalent doses of an immediate-release formulation, despite nearly identical areas under the curve [49], others recommend treatment if any APAP level is two-thirds or more of the one that is indicated toxic by the nomogram [27].

Chronic Overdose

There are occasional reports of serious toxicity from chronic overdose in infants with acute febrile illness [19,21]. Chronic toxicity has also been reported after doses only slightly higher than recommended and even with therapeutic ones in adults with fasting and alcohol use [50]. Although alcoholics do appear to be at greater risk for toxicity from therapeutic doses, the validity of data on fasting has been questioned [51]. There is no evidence that this occurs in otherwise healthy individuals. Similarly, in the absence of continued ethanol abuse, there is no evidence that therapeutic dosing carries an increased risk in patients with cirrhosis or other forms of chronic liver disease [52]. On the basis of current knowledge, there is no reason to avoid APAP in any of these groups, although patients must be clearly instructed to avoid overdosing.

Evaluation of patients with chronic overdose should include a detailed history of the timing of doses, particularly the last dose; the amount ingested at each dose; possible increased risk factors (e.g., chronic alcoholism, use of other P450 inducers); symptomatology; an APAP level at least 4 hours after the last dose; and aminotransferase levels. In such cases, the nomogram has never been studied and has little or no validity. Because there are currently no reliable guidelines to assess risk, it is best then to consult with a toxicologist or regional poison center to determine the best course of action. One approach is to treat according to the guidelines discussed in the next section.

Late Treatment

Treatment decisions in patients who present more than 24 hours after an overdose are problematic. Initial studies of the 20-hour intravenous NAC protocol suggested that NAC was of no value if started more than 12 to 15 hours after ingestion [28], and initial results of the 72-hour oral protocol indicated that treatment more than 16 hours after ingestion was
ineffective [30]. As a result, studies of treatment initiated after 24 hours were not performed initially. More extensive data and analyses of patients treated with 72 hours of oral NAC revealed that patients first treated between 16 and 24 hours after overdose experienced less hepatotoxicity than untreated historical control subjects or historical control subjects treated late with a 20-hour course of intravenous NAC [24].

Subsequently, a series of studies showed theoretical and clinical benefit to late NAC administration [29,53,54]. In the most remarkable of these, NAC started a median of 53 hours after ingestion and after evidence of severe liver injury reduced morbidity and mortality [29]. Although the issue of which cases warrant late treatment is not well defined, the following approach to the treatment of patients who present late is offered: If the APAP level is undetectable and aminotransferase levels are normal, NAC is not indicated, because the possibility of hepatotoxicity is extremely low. If hepatotoxicity is evident, a full course of NAC is indicated. For patients who have detectable APAP levels and no hepatotoxicity, NAC therapy should be started. It can be discontinued before completing a full course of therapy when the APAP concentration falls to zero, if aminotransferase levels remain normal.

Short-Course ORAL Treatment

Treatment of acute APAP overdose with an abbreviated course of oral NAC is based on the observation that treatment for 20 hours with intravenous NAC [28] and for 48 hours with oral NAC [36] is just as effective as treatment with oral NAC for 72 hours [24] when treatment is started within 8 to 16 hours of ingestion (see previous section), and that patients who develop hepatotoxicity exhibit laboratory evidence of such toxicity within 24 to 36 hours of ingestion [9,55]. In short-course protocols, oral NAC is initiated in patients with toxic or potentially toxic APAP levels (by the nomogram) in the same dose as used in the standard 72-hour regimen, and APAP levels and aminotransferases are obtained at 24 and 36 hours post-ingestion. As with late treatment, if the APAP level becomes undetectable and aminotransferase levels are normal at either point in time, NAC is stopped, whereas if hepatotoxicity becomes evident, a full course of NAC is indicated. For patients who have detectable APAP levels and no hepatotoxicity, NAC therapy should be continued. It can be discontinued before completing a full course of therapy if the APAP concentration subsequently becomes undetectable and if aminotransferase levels remain normal. Although toxicologists have been successfully using short-course NAC therapy for years, published data are limited [56], and poison centers have been slow to adopt this approach. Hence, consultation with a toxicologist is advised when contemplating
such treatment.
Severe hepatotoxicity after APAP overdose has traditionally been defined by an ALT or AST greater than 1,000 IU per L, although most patients with such elevations have no significant short- or long-term sequelae. Using this definition, the risk of hepatotoxicity can be estimated on the basis of the initial APAP concentration. Without NAC therapy, hepatotoxicity develops in less than 8% of all overdose patients, in 60% of probable risk cases (APAP concentration above a nomogram line intersecting 200 \( \mu \)g per mL at 4 hours and 50 \( \mu \)g per mL at 12 hours), and in 89% of high-risk cases (APAP concentration above a nomogram line intersecting 300 \( \mu \)g per mL at 4 hours and 75 \( \mu \)g per mL at 12 hours) [13].

Far less toxicity occurs in patients treated with NAC, although outcome depends on APAP concentration and the time NAC was started. Even in high-risk late-treated cases, only 41% of patients treated with oral NAC for 72 hours developed toxicity. Most important is that regardless of APAP level, NAC is extremely effective when started within 8 hours [24]. Hepatotoxicity occurred in less than 5% of patients in this subset.

Death is unusual after APAP overdose. When patients at probable risk for hepatotoxicity are considered, the reported mortality rate in untreated cases varies from 5.3% [28] to 24% [57]. A mortality rate of 1.1% has been noted in similar patients treated with the 20-hour intravenous NAC protocol [29], and it was found to be 0.68% in patients treated with the 72-hour oral NAC protocol [24]. In fact, even among high-risk cases first treated between 16 and 24 hours after overdose, the mortality rate was only 3.1% after oral NAC therapy [24].

It is not uncommon to see aminotransferase elevations greater than 10,000 IU per L during stage III, with eventual complete recovery [2]. As a result, aminotransferase levels alone are inadequate to judge prognosis. Evidence of hepatic dysfunction, such as marked elevations in prothrombin time and bilirubin, or evidence of persistent hypoglycemia, lactic acidosis, or hepatic encephalopathy, indicates true hepatic failure and a poor prognosis. Previous reports suggested that a bilirubin greater than 4 mg per dL or a prothrombin time greater than twice control indicates a poor prognosis [58]. More recently, a pH less than 7.30, prothrombin time greater than 100 seconds, serum creatinine greater than 3.4 mg per dL, and grade III or higher encephalopathy have been used to define poor prognosis [59], as has the single criterion of an increasing prothrombin time on day 4 after overdose (60) or a lactate of greater than 3.5 mmol per L shorter after admission [61]. More recently, Schmidt and Dalhoff [62] demonstrated that an increasing alpha-fetoprotein serum concentration (particularly a concentration of more
than $3.9 \, \mu g$ per L on the day after peak ALT) is associated with survival. As noted previously, patients meeting these criteria may benefit from NAC treatment \cite{29,53}. Standard measures for the treatment of liver failure, including arrangements for possible liver transplantation, should also be provided.

The presence or absence of aminotransferase elevation at the time of treatment initiation appears to be the most sensitive early prognostic indicator. To date, all reported patients who died from APAP toxicity already had some degree of AST or ALT elevation at the time a 72-hour course of oral NAC was started \cite{24}. Hence, all patients with liver enzyme values that are normal when oral NAC is started would be expected to survive.

3. Rumack BH. Acetaminophen overdose in young children. Treatment and effects of alcohol and other additional ingestants in 417 cases. *Am

The accidental or deliberate consumption of alcohols and glycols is a major cause of health problems. Although light consumption of ethanol may be associated with health benefits for some populations, heavy consumption increases overall mortality, especially mortality due to trauma, suicide, cirrhosis, and malignancies [1]. Ethanol is estimated to contribute to nearly 90,000 deaths each year in the United States, with economic costs in excess of $200 billion per annum [2]. The so-called toxic alcohols, namely, methanol and ethylene glycol, are usually involved in sporadic poisonings, often involving the accidental exposure of a young child to automotive or household products or the intentional suicidal ingestion of adults. Furthermore, multiple-victim poisonings can occur after recreational substitution for ethanol, during illicit manufacture of ethanol, or after the addition of other glycol products (see further discussion later).

ETHANOL

Ethanol is consumed by most adults and is the most serious drug of abuse among Western societies. Approximately one-third of the US population can be categorized as moderate-to-heavy drinkers, consuming four or more alcoholic drinks per week and of these, about one in five can be considered problem drinkers or alcoholics. Ethanol use is a factor in about 8% of emergency department visits [3] and 10% to 50% of hospital admissions, and its projected economic costs due to job absenteeism and poor job performance are substantial. Chronic ethanol consumption can cause multiorgan system disease, nutritional disorders, and teratogenic effects. In addition to beverages (typically 4% to 50% ethanol by volume), ethanol can be found in a myriad of other things such as colognes,
perfumes, mouthwashes, aftershaves, and over-the-counter medicinals. Many of these products contain ethanol and can be sources of intoxication, especially among children.

The chemical properties and kinetics of ethanol are summarized in Table 99.1. Ethanol is a small, slightly polar aliphatic alcohol with a weak electric charge and is miscible in water and lipids. It diffuses easily into all body tissues. It is postulated that ethanol influences multiple ion channels, possibly by causing subtle alterations in their tertiary structure or their dynamic interaction with cell membranes. The behavioral effects of ethanol may result from its ability to antagonize the excitatory N-methyl-D-aspartate–glutamate receptor and to potentiate the inhibitory γ-aminobutyric acid A receptor \([4–7]\). Ethanol is also known to interact with glycine, nicotinic acetylcholine, 5-HT\(_3\), and P\(_{2X}\) purinergic receptors, as well as the L-type calcium- and potassium-channel proteins \([8,9]\). The major metabolite, acetate, has been shown to mimic adenosine’s effects via the P\(_{1}\) receptor \([10]\). The precise role of these and other effects in producing intoxication, dependence, and withdrawal (see Chapter 126) is uncertain.

Data from references [75,80,81,86,91,92,94,103,104,107,110,127–129,145].

Ethanol is readily absorbed from the gastrointestinal tract, with 70% occurring in the stomach and 25% within the duodenum [11]. Peak ethanol levels typically occur 30 to 60 minutes after ingestion. Women have higher peak ethanol concentrations after a given dose because of smaller body mass and smaller relative body water, rather than gender differences of gastric mucosal alcohol dehydrogenase (ADH) activity [12].

Metabolism of ethanol occurs predominantly in the liver by three enzymatic systems: the cytosolic ADH enzyme family (especially class I), the cytochrome P450 enzymes (microsomal ethanol oxidizing system, largely CYP2E1 but also 3A4 and 1A2), and peroxisomal catalase [13,14]. Metabolism is Michaelis–Menten with zero-order kinetics prevailing at levels over 100 mg per dL [15]. Only a small fraction of ethanol is exhaled or secreted in urine and sweat [16].

ADH is responsible for greater than 57% of ethanol metabolism at low doses. In the ADH metabolic pathway (Fig. 99.1), ethanol is oxidized to
acetaldehyde and then to acetate in a process that reduces oxidized nicotinamide adenine dinucleotide (NAD\(^+\)) to nicotinamide adenine dinucleotide (NADH). The increased ratio of NADH to NAD\(^+\) can inhibit NAD\(^+\)-dependent reactions, such as gluconeogenesis, as well as slowing subsequent ethanol oxidation and clearance [17]. Acetate is linked to coenzyme A (acetyl-CoA), which can then participate in the citric acid cycle, fatty acid synthesis, or ketone formation [16]. Genetic variations of ADH and aldehyde dehydrogenase have been extensively characterized and may play a role in determining susceptibility to alcoholism [18,19]. Normally, the cytochrome P450 and catalase systems play minor roles in ethanol metabolism. Chronic ethanol use can induce CYP2E1 activity 4- to 10-fold, allowing habitual users to metabolize ethanol twice as quickly as occasional drinkers [20].
Ethanol is a central nervous system (CNS) depressant. After acute ingestion, there is often an initial stage of paradoxical excitation because of release of inhibitions. For nontolerant individuals, a blood ethanol concentration as low as 20 mg per dL impairs driving-related skills involving perception and attention [21]. At concentrations of 50 mg per dL, gross motor control and orientation may be affected, and intoxication may become apparent [22]. Lethargy, ataxia, and muscular
incoordination may be seen at serum levels of 150 mg per dL or greater, coma at approximately 250 mg per dL, and death with levels greater than 450 mg per dL [23,24]. Tolerant drinkers can achieve higher levels before developing similar symptoms, and survival has been reported despite a serum level of 1,500 mg per dL [11,25]. At high doses, ethanol functions as an anesthetic, causing CNS depression, autonomic dysfunction (e.g., hypotension, hypothermia), coma, and death from respiratory depression and cardiovascular collapse. The estimated LD$_{50}$ in adults is 5 to 8 g per kg and 3 g per kg for children [23].

Tolerance to ethanol’s effects develops both acutely and after chronic consumption. With acute consumption, the physiologic effects at a given serum level of ethanol have been noted to be less when ethanol concentrations are declining rather than when levels are rising (Mellanby effect). Compared with inexperienced drinkers, chronic drinkers experience diminished effects to a given amount of ethanol. Tolerance is accompanied by changes in membrane-associated receptors.

Clinical Manifestations
Patients may present with varying degrees of altered consciousness, including agitation, stupor, and coma. The odor of ethanol or its congeners on their breath is usually present. Slurred speech, ataxia, and nystagmus are noted in patients with mild to moderate intoxication. Disconjugate gaze is frequently seen in comatose patients. Acute intoxication may be accompanied by vomiting, particularly in novice drinkers.

Diagnostic Evaluation
The physical examination should be directed toward evaluation of the airway and a search for complicating or contributing factors such as trauma, infection, and hemorrhage. For patients with moderate-to-severe poisoning, laboratory studies including complete blood cell count; serum electrolytes, blood urea nitrogen, creatinine, glucose, ethanol, magnesium, calcium, and phosphorus level; liver function tests; prothrombin time; electrocardiogram; chest radiograph; arterial or venous blood gas; and urinalysis should be obtained as clinically indicated. Blood alcohol levels may be helpful to support the diagnosis, but it does not predict clinical severity or overall outcomes [11]. If the level of consciousness is inconsistent with the serum ethanol level or does
not improve over a few hours, the physician should reconsider the diagnosis of ethanol intoxication (Table 99.2).

Management
Patients with stupor or coma who cannot be aroused to a verbal (but not necessarily coherent) state or who have a poor respiratory effort should be intubated to ensure airway patency and to protect against pulmonary aspiration. Intravenous (IV) naloxone (0.1 to 2 mg), dextrose (25 to 50 g), and thiamine hydrochloride (100 mg) should be administered when opioid toxicity, hypoglycemia, or Wernicke’s encephalopathy are considerations.

Activated charcoal should be withheld unless potentially toxic coingestants are suspected. Hypothermia, when present, is usually mild in the absence of environmental exposure and can be managed with warm blankets. Nutritional, electrolyte, and fluid deficiencies should be corrected. A variety of interventions trying to increase ethanol clearance or decrease its effects are neither clinically useful nor recommended.
ALCOHOLIC KETOACIDOSIS

Alcoholic ketoacidosis (AKA) develops as a result of hormonal, nutritional, and metabolic changes caused by ethanol (Fig. 99.2). Because ethanol retards ketogenesis, AKA usually occurs when ethanol levels are low to absent [16]. Ethanol metabolism indirectly impairs gluconeogenesis and increases fatty acid and ketone formation. Inadequate nutritional intake of alcoholics depletes glycogen, mineral, and vitamin stores. Vomiting results in decreased intravascular volume and increased catecholamine levels that blunt insulin release [26] activate lipase and accelerate free fatty acid oxidation. Glucagon activates the carnitine acyltransferase system, producing excess acetyl-CoA.

**FIGURE 99.2** Mechanism of alcoholic ketoacidosis. Co, coenzyme; FFA, free fatty acids; NAD⁺, oxidized form of nicotinamide adenine dinucleotide; NADH, nicotinamide adenine dinucleotide; TCA, tricarboxylic acid cycle (also known as citric acid cycle).

Acetyl-CoA cannot be used by mammals to form pyruvate or higher carbohydrates. Instead, it can undergo only three metabolic fates: fatty acid synthesis, oxidation to CO₂ in the citric acid cycle, and cholesterol or ketone body formation via 3-hydroxy-3-methylglutaryl-CoA. The ketogenic pathway has the largest capacity and requires the least
adenosine triphosphate for handling acetyl-CoA overload [26]. Nutritional deficiencies impair acetyl-CoA conversion to triglycerides and its entrance into the citric acid cycle [16]. Finally, the increased NADH-to-NAD\(^+\) redox ratio caused by ethanol oxidation favors the conversion of acetoacetate to $\beta$-hydroxybutyrate, which is largely responsible for the ketoacidosis.

Other acid–base abnormalities may occur among alcoholics. Respiratory acidosis may be caused by hypoglycemia or ethanol-induced respiratory depression. Lactic acidosis can occur secondary to seizure activity, an increase in the NADH-to-NAD\(^+\) ratio that favors lactate formation from pyruvate, decreased gluconeogenesis, thiamine deficiency impairing pyruvate’s entry into the citric acid cycle, and liver dysfunction [14,27]. Vomiting may cause volume contraction, hypokalemia, and metabolic alkalosis [14,26]. A mild acetic acidosis may be seen when peripheral tissues incompletely oxidize acetate. A hyperchloremic metabolic acidosis has been observed among acutely intoxicated patients who have excreted $\beta$-hydroxybutyrate in their urine [27].

Clinical Manifestations

Patients with AKA usually present with a recent history of binge alcohol drinking in the setting of chronic alcohol use and poor nutritional intake followed by vomiting and abdominal pain. The fruity odor of ketones may be detected along with Kussmaul’s breathing, dry mucous membranes, tachycardia, orthostatic hypotension, and poor skin turgor [16]. Abdominal pain is typical, with nonspecific tenderness on examination [14].

Diagnostic Evaluation

The diagnosis of AKA is a diagnosis of exclusion. Signs and symptoms of concomitant gastritis, pancreatitis, hepatitis, gastrointestinal hemorrhage, and vitamin and mineral deficiencies are often present. Laboratory studies should include those listed for acute ethanol intoxication plus serum ketones, lactate, and osmolality. Ethanol levels are often low to undetectable, and hypoglycemia may be present [28]. A respiratory or metabolic alkalosis may be present in addition to the anion gap metabolic acidosis. At presentation, the predominant serum ketone is usually $\beta$-hydroxybutyrate because of the altered redox state, which results in falsely low serum ketones by the semiquantitative nitroprusside test for acetoacetate [16]. Many laboratories now measure $\beta$-
hydroxybutyrate directly to mitigate this concern. Hypokalemia is uncommon, in part because acidosis shifts potassium out of the cell. The osmol gap may be elevated from glycerol, acetone, and its metabolites [29], even after correcting for the serum ethanol concentration [30,31].

The differential diagnosis of an anion gap metabolic acidosis includes lactic acidosis, salicylate poisoning, uremia, diabetic ketoacidosis, and intoxication from iron, ibuprofen, toluene, methanol, ethylene glycol, and diethylene glycol. AKA can usually be differentiated from diabetic ketoacidosis by the lack of significant hyperglycemia, minimal alteration of consciousness, a relatively mild acidosis, and rapid improvement with supportive therapy [32]. The presence of more than mild tenderness on abdominal examination should prompt investigation for other pathology such as pancreatitis, hepatitis, sepsis, or pneumonia [14].

**Management**

Supportive therapy is the same as that noted for acute intoxication. IV fluid resuscitation, glucose (25 to 50 g), and thiamine (100 mg) reverse the ketogenic process and are the mainstays of therapy. Maintenance fluids should consist of dextrose (5%) in normal saline [14,30]. Thiamine facilitates the entry of pyruvate into the citric acid cycle and protects against Wernicke’s encephalopathy [33]. Once urine output is established, supplemental potassium and magnesium should be administered. Hypophosphatemia may develop with increased glycolysis and carbohydrate refeeding and should be corrected with potassium phosphate [32,34]. Hospitalization and refeeding of malnourished patients may be required.
ETHYLENE GLYCOL AND METHANOL

Ethylene Glycol

Ethylene glycol (1,2-ethanediol) is a colorless, sweet liquid [35] that imparts a warm sensation to the tongue and esophagus when swallowed. It is found primarily in automotive antifreeze and de-icing solutions. Ingestions usually result from suicide attempts, intentional substitution of ethylene glycol for ethanol, or accidental exposure. According to the Annual Report of the American Association of Poison Control Centers’ National Poison Data System (NPDS) during 2014 poison centers received 6,078 calls about ethylene glycol [36], including 2,134 cases treated in a health care facility and 16 deaths. Ethylene glycol itself causes little toxicity other than ethanol-like inebriation until it is metabolized in the liver into its toxic acid metabolites (Fig. 99.3). Ethylene glycol is first metabolized in the liver by ADH to glycoaldehyde, which is rapidly transformed via aldehyde dehydrogenase to glycolic acid. Glycolic acid is slowly converted to glyoxylic acid, which in turn is converted to multiple metabolites, including oxalic acid [37,38]. It is uncertain which of these metabolites is most directly responsible for renal tubular toxicity, though recent studies suggest that internalization of calcium oxalate crystals by proximal tubule cells may be directly related to renal damage [39].
The anion gap metabolic acidosis seen in ethylene glycol poisoning is due predominantly to elevated glycolic acid levels [37,40], although oxalic acid, glyoxylic acid, and glycoaldehyde may be more toxic [39]. Elevated lactic acid levels contribute to the acidosis [40,41] and have been attributed to the increased NADH-to-NAD\(^+\) ratio caused by metabolism of ethylene glycol [42,43] and to the toxicity of glyoxylic acid on mitochondrial respiration [37]. Some lactate assays may misinterpret glycolate as lactate and report falsely elevated lactate levels [44–46].

Pathologic changes are noted in the CNS, kidneys, lungs, heart, liver, muscles, and retina [23,47]. Renal findings include dilation of the proximal tubules with swelling and vacuolization of the epithelial cells,
distal tubular dilation, intratubular deposition of calcium oxalate crystals, and interstitial edema [42]. Pulmonary edema, interstitial pneumonitis, and hemorrhagic bronchopneumonia may occur. In some cases, interstitial myocarditis, skeletal muscle inflammation, and centrilobular hepatic fatty infiltration may develop. CNS findings include cerebral edema, meningoencephalitis, and cerebellar changes, including focal loss of Purkinje cells [47].

The chemical properties and kinetics of ethylene glycol are summarized in Table 99.1. Oral absorption of ethylene glycol occurs rapidly. Percutaneous absorption through intact skin is negligible. Ethylene glycol has a high boiling point and toxicity from vapor inhalation does not occur. Hepatic metabolism predominates, yet renal elimination of the parent compound is initially substantial. The ensuing renal failure markedly prolongs the elimination of ethylene glycol and its metabolites [42,48,49].

The estimated minimum lethal dose is 1.4 mL per kg body weight for humans [35]. With early and intensive treatment, survival has been reported in patients with serum ethylene glycol concentrations as high as 1,889 mg per dL [50].

**Methanol**

Methanol is a colorless liquid and has an odor distinct from that of ethanol. Dietary sources and endogenous metabolism can produce serum methanol levels of 0.15 mg per dL [51]. Exogenous sources of methanol include windshield washing fluid, de-icing fluids, carburetor cleaners, paint removers, and paint thinners. The NPDS reports that during 2014 there were 1,825 calls to poison centers regarding methanol and 9 associated deaths [36].

Methanol is oxidized in the liver by ADH to formaldehyde, which is quickly converted to formic acid (formate) by hepatic aldehyde dehydrogenase (Fig. 99.4). In primates, formate accumulates because of saturation of one-carbon metabolism. High levels of formate, an inhibitor of mitochondrial cytochrome oxidase, cause histotoxic hypoxia and are responsible for the characteristic metabolic acidosis and ocular toxicity seen with methanol toxicity [52]. Formaldehyde is also very toxic, but it has a very short half-life [53].
Formate plays a pivotal role in methanol toxicity. Blood formate concentrations account for nearly the entire observed anion gap and base deficit [54]. Symptoms and prognosis also correlate better with formate than with methanol levels [55,56]. Primates infused with formic acid develop ocular toxicity, even when the acidosis is controlled with sodium bicarbonate [57]. Ocular toxicity results from the inhibition of cytochrome oxidase by formic acid in the optic nerve, leading to disruption of mitochondrial electron transport and decreased axoplasmic flow and electrical conduction [58]. Direct retinal toxicity can also occur.
The chemical properties and kinetics of methanol are summarized in Table 99.1. Methanol is absorbed orally, dermally, and via inhalation [60]. Exposure can occur intentionally or accidentally, including mass outbreaks, as occurred in Estonia in 2001 when 68 patients died after consuming illegal spirits contaminated with methanol [61]. Adults who abuse carburetor cleaning fluid by inhalation can achieve serum methanol levels greater than 50 mg per dL [62]. Methanol’s metabolism is slower than that of ethylene glycol or ethanol [42,53]. Hepatic oxidation predominates, with only trivial amounts eliminated via the lungs and kidneys [53]. Elimination follows first-order kinetics at low doses and during hemodialysis [63–65]. At higher doses, zero-order (Michaelis–Menten) kinetics may prevail. In one untreated patient, methanol elimination occurred at a rate of 8.5 mg/dL/h [66]. The elimination half-life of formate in one untreated patient was 3.7 hours [67] and averaged 3.4 ± 1.5 hours in eight patients treated with fomepizole (4-methylpyrazole) and leucovorin [54]. With hemodialysis, the formate elimination half-life was estimated to be between 1.8 and 3.1 hours [54,67].

Reported lethal doses for patients with inadequate, delayed, or no therapy vary considerably and are not well established. In one epidemic, the minimal lethal dose was 15 mL of a 40%-by-weight methanol solution. Yet, in a case report a 27-year-old man with a blood methanol concentration of 1,290 mg per dL (12.9 g per L), possibly ingesting up to 1,000 mL of a 60%-by-weight methanol solution, survived with moderate visual sequelae and esophageal stenosis [68].

Clinical Manifestations

Ethylene Glycol

Ethanol-like intoxication usually begins within an hour of ingestion. Symptoms due to toxic metabolites usually occur 4 to 12 hours after ingestion, but are delayed further if ethanol was coingested by delaying the metabolism of ethylene glycol. Patients may present alert, intoxicated, or in a coma, depending on the time since ingestion, the dose of ethylene glycol, coingestion of ethanol, and cross-tolerance [42,47]. Vital signs can be normal. Ocular exposure can produce a chemical conjunctivitis and chemosis [47], but systemic toxicity does not occur.

The classic division of ethylene glycol poisoning into three stages is primarily of historical interest. In reality, patients rarely exhibit sequential toxicity that can be readily divided into distinct stages. Shortly after ingestion and before significant metabolism of ethylene glycol has occurred, CNS effects such as ethanol-like intoxication, stupor, nausea,
and vomiting predominate. As toxic metabolites begin to accumulate, a metabolic acidosis ensues with associated cardiovascular and pulmonary signs, including Kussmaul’s respirations, tachycardia, cyanosis, and cardiogenic or noncardiogenic pulmonary edema. As renal injury progresses, flank pain and tenderness, proteinuria, and anuria may occur. Acute renal failure occurs in nearly all untreated patients who manifest metabolic acidosis (serum bicarbonate <10 mmol per L). Renal dysfunction can develop within 9 hours of ingestion [69]. Patients may also develop myositis with muscle tenderness and elevated creatine kinase [42]. Death may result from severe metabolic derangements, cardiovascular or respiratory failure, or progressive CNS depression. Prolonged seizures, coma, and a cerebral herniation syndrome have also been reported [70]. Preterminal dysrhythmias and hypotension are rare. The presence of hyperkalemia, severe acidemia, seizures, and coma at presentation demonstrate severe toxicity.

Seizures are usually generalized but do not occur in all cases. Jacksonian seizures have been reported, as have myoclonic jerks and tetanic contractions due to hypocalcemia [47]. Progressive CNS depression and prolonged seizures usually result from cerebral edema [42]. Transient nystagmus and cranial nerve (II, V, VI, VII, VIII, IX, and X) palsies have been reported to occur 4 to 18 days postingestion [35,50,70–73].

**Methanol**

Onset of toxicity usually occurs within 30 hours of methanol ingestion. In one epidemic, a range of 40 minutes to 72 hours was reported. Factors influencing time to symptoms include the dose, ethanol coingestion, and folate stores.

Neurologic, ophthalmologic, and gastrointestinal symptoms predominate. Methanol is a less potent CNS depressant than ethanol. Patients may be alert on admission and complain only of headache and dizziness. Amnesia, restlessness, acute mania, lethargy, confusion, coma, and convulsions may follow. Cases mimicking subarachnoid hemorrhage with severe headache, vomiting, hypertension, and bradycardia followed by loss of consciousness have been described. Dyspnea is reported by only 8% to 25% of patients [61].

Early on, many patients offer no visual complaints. Visual symptoms accompany the metabolic acidosis and usually develop when the blood pH falls below 7.2. Blurred vision, photophobia, scotomata, eye pain, partial or complete loss of vision, and visual hallucinations (e.g., bright lights, “skin over eyes,” “snowstorm,” dancing spots, flashes) have been reported. These disturbances can persist after formate has been completely eliminated and the acidosis has resolved.
Methanol can produce severe hemorrhagic gastritis and pancreatitis, causing upper abdominal pain, nausea, vomiting, and diarrhea. Liver function abnormalities have been documented in moderately to severely ill patients.

Vital signs may reveal tachycardia and Kussmaul’s respirations, but the blood pressure is usually maintained. Untreated, patients can die from sudden respiratory arrest [74]. The skin may be cool and diaphoretic, and abdominal muscles rigid without rebound tenderness.

The most notable physical findings are those discovered on ophthalmologic examination, but these are late findings. Pupils may react sluggishly or may be fixed and dilated. Funduscopic examination may show hyperemia of the optic discs followed by retinal edema, which develops initially along the retinal vessels and then spreads to the central areas of the fundus. Retinal vessel engorgement accompanies the retinal edema [52]. Papilledema may develop [7]. Ophthalmologic findings do not necessarily correlate with visual complaints.

Diagnostic Evaluation

Poisoning by ethylene glycol and methanol should be suspected for all patients with a history of ingesting ethanol substitutes or who have an unexplained anion gap metabolic acidosis.

Ethylene Glycol

Laboratory studies should include complete blood cell count; serum electrolytes; glucose; blood urea nitrogen; creatinine; arterial or venous blood gas; calcium; serum osmolality; ethanol, methanol, and ethylene glycol levels; and urinalysis. Additional laboratory studies may include electrocardiogram, chest radiograph, and head computed tomography as clinically indicated. Early after ingestion, before significant metabolism of ethylene glycol, an osmol gap may be present with neither metabolic acidosis nor an anion gap (see later discussion on osmol gap). As ethylene glycol is metabolized, the osmol gap decreases and an anion gap metabolic acidosis develops. Patients who present very late may have renal failure with normal osmol and anion gaps, normal pH, and unmeasurable ethylene glycol levels.

Perhaps the greatest diagnostic challenge of managing a patient suspected to have ingested a toxic alcohol or glycol is the limited availability of methanol and ethylene glycol testing. Gas chromatography
can reliably quantify the presence of ethylene glycol or methanol, but most hospitals are unable to obtain these tests in a timely fashion. Moreover, some hospitals offer a “toxic alcohol screen” that detects methanol, ethanol, and isopropanol but not ethylene glycol, which is a diol. This nomenclature can mislead a clinician into interpreting a negative “toxic alcohol screen” as excluding the presence of ethylene glycol. Interference due to propionic acid, propylene glycol, glycerol, 2,3-butanediol, and β-hydroxybutyrate has been described [75–78]. Testing for glycolic acid or formic acid is even less available. A rapid bedside qualitative test for ethylene glycol is available but not yet approved for diagnostic use in humans [79]. Breath alcohol analysis can mistake methanol for ethanol, providing indirect evidence of exposure. Therefore, diagnostic and therapeutic decisions are often based on circumstantial evidence derived from the history and available laboratory testing, pending confirmatory testing. It is essential for the physician to understand the strengths and the limitations of these indirect markers of toxicity.

Arterial pH measurements in ethylene glycol–exposed patients can range from 6.7 to 7.5 [69]. Ethylene glycol poisoning often results in higher anion gaps than other causes of this abnormality [56,43,80,81]. The differential diagnosis of an increased anion gap metabolic acidosis is discussed above (see “Alcoholic Ketoacidosis” section). In young children, child abuse and inborn errors of organic acid metabolism should be considered in the differential diagnosis [78,82]. Hyperkalemia may be seen in association with acidosis and with renal failure [47,83,84]. The creatinine and blood urea nitrogen are normal unless renal failure has supervened. Calcium levels are initially normal but may drop significantly as calcium complexes with oxalic acid to form calcium oxalate. The electrocardiogram may show ST-T wave and QTc changes consistent with hypocalcemia, hyperkalemia, or both.

The osmol gap (refer to Chapters 97, 137, and 198) is frequently used as a diagnostic test in the evaluation of these patients. Extreme caution must be used when interpreting the osmol gap, however. First, the serum osmolality should be measured by the freezing point depression, as vapor pressure osmometry will not detect methanol, ethanol, and isopropanol.

Although an osmol gap greater than 10 mOsm is often sought as indirect evidence of the presence of an exogenous alcohol or glycol, failure to find an elevated osmol gap does not rule out significant alcohol or glycol ingestion [80]. Cumulative measurement error in the formula parameters, variations of the formula itself, and the natural variability in the osmol gap at baseline contribute to imprecision in the calculated osmol gap [30,85,86]. This variability can hide a significant amount of an alcohol or glycol. Furthermore, as the parent alcohol or glycol is oxidized to the toxic-charged metabolite, the osmol gap
disappears. Conversely, an elevated osmol gap is not specific for alcohols or glycols, as lactic acidosis, ketoacidosis, and sepsis can also increase the osmol gap [80].

In studies of various control populations not exposed to methanol, isopropanol, or ethylene glycol, osmol gaps averaged approximately −1 to −2 mOsm per kg [31,87,88]. The variability was substantial, however, with standard deviations of between 5 and 8 mOsm per kg. Thus, although an arbitrary upper limit of 10 mOsm per kg has historically been used for the normal osmol gap, an osmol gap of 10 mOsm per kg in a patient whose usual baseline gap is 0 could represent substantial serum concentrations of ethylene glycol (62 mg per dL) or methanol (32 mg per dL) [81]. One patient with an osmol gap of only 11 mOsm per kg had an ethylene glycol level of 38 mg per dL and subsequently developed renal failure [43], whereas another patient with an osmol gap of 7.2 mOsm per kg required hemodialysis for ethylene glycol toxicity [89]. Thus, an elevated osmol gap may suggest the presence of an alcohol or glycol, but a normal gap does not rule out a small ingestion or a late presentation.

Microscopic examination of the urine for crystals is another indirect diagnostic test frequently recommended. Less than 50% of patients have crystalluria at presentation, however. Calcium oxalate monohydrate (needle-shaped) and calcium oxalate dihydrate (envelope-shaped) crystals can both be seen, but the monohydrate may be confused with uric or hippuric acid crystals [43,90]. The dihydrate crystals tend to occur at higher concentrations and convert to the monohydrate form within 24 hours [91], but are also nonspecific and can be found in the urine after ingestion of oxalate-containing foods such as rhubarb. Other nonspecific urinary findings can include low specific gravity, proteinuria, hematuria, and pyuria. Some antifreeze manufacturers add fluorescein to their products to facilitate the detection of radiator leaks. Wood’s lamp examination of the urine or gastric aspirate to detect fluorescence is unreliable and should not be used to make or exclude the diagnosis. Other drugs, food products, toxins, and even endogenous compounds cause urine to fluoresce, as do the containers used to collect urine [92,93].

**Methanol**

The laboratory studies listed for ethylene glycol evaluation should be obtained. Methanol can also cause an anion gap metabolic acidosis and an osmol gap [35]. The caveats noted under ethylene glycol for the evaluation and interpretation of these parameters apply equally to methanol. Elevated lactate levels, mild hypokalemia, and leukocytosis may occur. Lactic acidosis may be seen late in the course of methanol poisoning and may result from inhibition of the mitochondrial electron
transport system or from poor tissue perfusion [42]. Serum lactate concentrations of 11.5 and 23 mmol per L have been reported 24 hours or more after ingestion. Amylase elevations and pancreatitis can occur in up to one-half of severely poisoned patients [66,94]. Computed tomography scanning can demonstrate cerebral edema, as well as frontal lobe and basal ganglia hemorrhages and infarcts associated with poor clinical outcomes.

Management

The focus of treatment for ethylene glycol and methanol poisoning is to prevent the formation of toxic metabolites by inhibiting liver ADH and enhancing the removal of the parent compound and metabolites. Antidotal therapy, cofactor therapy, and hemodialysis may be necessary in addition to supportive care to achieve these goals.

Initial treatment includes airway management in the comatose patient, IV fluids, cardiac monitoring, and appropriate laboratory studies. Gastric aspiration via a nasogastric tube may be beneficial when performed within an hour of an intentional ingestion. Oral activated charcoal is ineffective, but may be considered when coingestants are suspected [95,96]. IV sodium bicarbonate should be administered to correct serum pH to at least 7.3 [66,96]. Large doses of sodium bicarbonate may be required. Sodium bicarbonate is useful in ethylene glycol and methanol poisonings for three reasons. First, unlike the metabolites in lactic acidosis and ketoacidosis, the metabolites of ethylene glycol and methanol cannot be transformed to regenerate bicarbonate [43], and the acidosis must be corrected with exogenous alkali. Second, increasing the serum pH enhances the ionization of acid metabolites, making them less diffusible, trapping them in the blood and extracellular fluid, and limiting their tissue penetration [42]. Third, urinary alkalinization may increase excretion of acid metabolites through ion trapping, provided renal function remains normal [35,90]. In ethylene glycol poisoning, however, the hypocalcemia that occurs as calcium complexes with oxalate may be worsened by alkali administration. Calcium chloride/gluconate should be administered to correct symptomatic hypocalcemia including seizures, but the indiscriminate use of calcium salts to correct a laboratory value should be avoided because it may increase the precipitation of calcium oxalate crystals [97]. In methanol poisoning, increasing the serum pH may increase the concentration of ionized formate, thus diminishing formic acid access to the CNS and possibly ameliorating retinal toxicity [42].
Seizures should initially be treated with standard anticonvulsants, such as benzodiazepines and barbiturates. Hypocalcemia and hypoglycemia should be excluded. Recurrent or persistent coma or seizures should prompt evaluation for underlying cerebral edema. Cerebral edema should be managed acutely with hyperventilation, mannitol (provided renal function is intact), and potentially intracranial pressure monitoring and decompression. Cardiopulmonary complications may require inotropes and vasopressors.

Ethanol and fomepizole are antidotes for ethylene glycol and methanol poisoning. These agents inhibit liver ADH, and block the initial oxidation of ethylene glycol and methanol to their more toxic metabolites. After ADH is inhibited, ethylene glycol and methanol can be eliminated via endogenous or extracorporeal routes \([49,98,99]\). Antidotal therapy has no effect on the elimination of the acid metabolites. Indications for antidotal therapy in cases of known or possible methanol or ethylene glycol intoxication are outlined in Table 99.3 \([69,84,96,100]\).

<sup>a</sup>Attempts should be made to obtain confirmatory methanol or ethylene glycol concentrations as soon as possible when contemplating alcohol dehydrogenase inhibitor therapy. In all cases, consultation with a medical toxicologist is strongly recommended.
Recognition that ethanol is the preferred substrate for ADH (10 to 20 times greater affinity for ADH than other alcohols) [35] suggested its clinical use as a competitive inhibitor of this enzyme. Although most sources recommend administering sufficient ethanol to maintain serum ethanol concentrations between 100 and 150 mg per dL [63], limited data support this target concentration. Because ethanol is a competitive inhibitor of ADH, extremely high levels of ethylene glycol or methanol must by necessity be met with higher doses of ethanol. Targeting a 1:4 molar ratio [42,101] a serum ethanol concentration of 100 mg per dL should suffice for methanol concentrations as high as 257 mg per dL or ethylene glycol as high as 540 mg per dL. Dosage guidelines to achieve an ethanol concentration of 100 mg per dL are outlined in Table 99.4.

### Table 99.4 Ethanol Dosing for Ethylene Glycol or Methanol Poisoning

</tr>
<tr>
<td>Intravenous: use 5%–10% concentration, load over 1 h (e.g., 10 mL/kg of 10% ethanol in D5 W over 1 h)</td>
</tr>
</tbody>
</table>

If ethanol is already present, the amount of ethanol required to achieve a serum ethanol level of 100–150 mg/dL may be calculated as follows:

\[
\text{Amount ethanol (mg)} = [\text{desired concentration (mg/dL)} - \text{known concentration (mg/dL)}] \times \text{V}_d \text{ of ethanol (0.6 L/kg)} \times \text{body weight (kg)} \times 10 \text{ dL/L}
\]

**Maintenance doses of ethanol:**

Begin during administration of the loading dose.

Give 80 mg/kg/h of ethanol orally or intravenously (as above). For a patient on hemodialysis, the maintenance dose should be higher: 250–350 mg/kg/h. Chronic alcoholics also require higher doses (average 150 mg/kg/h). Because of potential hypoglycemia, glucose should be given along with ethanol. Serum ethanol and glucose levels must be monitored frequently.

---

D5 W, dextrose 5% in water; Vd, volume of distribution.
There are disadvantages to using ethanol therapeutically. Perhaps the most important limitation is the toxicity of ethanol itself, including coma, airway compromise, respiratory depression, and agitation [16,102,103]. At recommended doses, ethanol induces inebriation in the nontolerant individual. Subsequent behavioral effects and severe mental status depression may require interventions, such as sedation and endotracheal intubation shortly after initiation of therapy. The need for these interventions as well as the continuous infusion of ethanol itself can complicate and delay interfacility transfer. Although IV ethanol administration is generally preferred to oral ethanol, this requires extemporaneous compounding from dehydrated ethanol and an infusion of a hypertonic solution (10% ethanol by volume is 1,700 mOsm per kg), usually via a central venous catheter. Maintaining an adequate ethanol level can be difficult and interindividual variation in metabolism and removal during hemodialysis necessitate frequent monitoring of serum concentrations and dosage adjustments [102]. This allows for more opportunity for ethanol-related medication errors, such as excessive ethanol dose, inadequate monitoring, and inappropriate antidote duration, as compared with fomepizole therapy [104]. Finally, ethanol therapy is relatively contraindicated in patients on disulfiram or similar medications, patients with hepatic disease, and patients with alcohol addiction. Admission to an intensive care setting is considered mandatory for an individual receiving ethanol therapy.

Given these limitations to ethanol therapy, fomepizole has emerged as the preferred antidote. It is a more potent competitive inhibitor of ADH, with 500 to 1,000 times greater affinity for ADH than is ethanol [35,90,97,105,106]. Fomepizole has many advantages over ethanol: wide therapeutic margin, ease of administration, fixed dosing schedule, lack of CNS or behavioral toxicity, lack of metabolic or fluid balance effects, patient and provider safety, and no need for drug concentration monitoring [95,103,105,107,108]. Despite these advantages, ethanol should not be overlooked as a viable treatment option during mass outbreaks or times of limited resources or drug availability [109]. Currently, fomepizole is only available in a parenteral formulation, although oral administration of this same formulation has similar pharmacokinetics and efficacy [110]. Highly selected patients treated with fomepizole may also avoid hemodialysis (discussed later), intensive care unit admission, or even interfacility transfer [48,49,90,95,106,107,110–115]. These advantages are even more important in the setting of mass epidemics and in pediatric exposures [116].
A minimum serum fomepizole concentration of 10 µM (0.8 mg per dL) [117] effectively halts ethylene glycol and methanol oxidation [49,118] and is much higher than the in vitro $K_i$ of fomepizole for human ADH of 1 µM [119]. Recommended dosing (Table 99.5) achieves and maintains serum fomepizole concentrations greater than 100 µM, eliminating the need for drug concentration monitoring [120]. Adverse drug events associated with fomepizole therapy are infrequent, but include rash, eosinophilia, minimal hepatic transaminase elevations, nausea, vomiting, and abdominal pain [121]. Hypersensitivity to pyrazoles, such as celecoxib and zaleplon, is the only contraindication to its use. Fomepizole does not appear to affect retinol dehydrogenases involved in vision [122]. Its dosing protocol is based on zero-order elimination kinetics, increased clearance during hemodialysis, and potential autoinduction of metabolism via cytochrome P450–2E1 [123,124] (Table 99.5).

The main disadvantage to fomepizole therapy is the higher acquisition cost of the drug compared with ethanol [125,126], although this
acquisition cost must be balanced against improved patient safety and reduced intensity of monitoring and therapy [107,113,127]. Although there are no prospective clinical studies directly comparing the safety of ethanol with fomepizole, there are retrospective evaluations that have reported fewer adverse drug events with fomepizole [102,128]. Fomepizole is the antidote of choice, when available [126], especially for a patient who has coingested other CNS depressants, for the critically ill patient with a profound anion gap metabolic acidosis of uncertain etiology, and for the patient in whom hemodialysis may be technically challenging (e.g., infants) or unnecessary [95,108,129].

Fomepizole has also been successfully used to treat combined methanol/isopropanol [130] and diethylene glycol/triethylene glycol [112] overdose in humans. Treatment with fomepizole or ethanol should be continued until the metabolic acidosis has resolved and serum methanol or ethylene glycol levels fall below 20 mg per dL (200 mg per L).

Cofactor therapy for patients poisoned by ethylene glycol includes IV pyridoxine (100 mg) and thiamine (100 mg) once a day until ethylene glycol levels are unmeasurable and acidemia has cleared. Pyridoxine is required for the conversion of glyoxylic acid to glycine, whereas thiamine and magnesium are required for the conversion of glycolic acid to γ-hydroxy-α-ketoAdipate. Administering these cofactors may shunt metabolism away from the formation of oxalic acid [83,131], although benefit has not been documented in human poisonings. Magnesium should be administered to patients with hypomagnesemia.

Patients poisoned with methanol should receive IV folinic acid (leucovorin), 1 to 2 mg per kg every 4 to 6 hours until methanol and metabolic acidosis have been cleared [67,97]. Folic acid (folate) can be substituted if leucovorin is unavailable. Hepatic formate metabolism occurs through a folate-dependent mechanism (see Fig. 99.4). The susceptibility of primates to methanol toxicity correlates with reduced hepatic 5,6,7,8-tetrahydrofolate (THF, or reduced folate) stores compared with lower mammals [97], and exogenous folinic acid (5-formyl-THF) or folate may increase their capacity to remove formate. Although human data are limited, monkeys pretreated with folic or folinic acid resulted in marked attenuation of serum formate levels and metabolic acidosis after methanol administration [132]. Folinic acid given after the onset of methanol toxicity was also beneficial.

Hemodialysis effectively removes ethylene glycol, methanol, glycolic acid, formic acid, and probably the other toxic metabolites and should be used in nearly all cases with acidosis or end-organ toxicity [35,48,53,54,56,63,133]. Early hemodialysis can prevent subsequent toxicity [8,91]. Addition of extra sodium bicarbonate to the dialysate can assist in correcting acidosis, and hemodialysis may assist in controlling
The frequency of fomepizole dosing must be increased during hemodialysis to compensate for its removal. When using ethanol, its infusion rate should be empirically doubled at the start of hemodialysis, and serum ethanol levels should be monitored hourly.

Recommendations for hemodialysis are outlined in Table 99.6 [35,48,50,53,97,98,107,108]. Traditional criteria for hemodialysis have included a serum ethylene glycol or methanol concentration >50 mg per dL (500 mg per L), independent of symptoms, acid–base status, or other markers of end-organ toxicity [97], but selected patients have been successfully managed with fomepizole, cofactors, and IV fluid hydration alone despite serum ethylene glycol concentrations >400 mg per dL, although consultation with a toxicologist is strongly recommended [49]. Such patients must be hemodynamically stable and have near normal acid–base status and renal function. If minimal ethylene glycol metabolism has occurred before initiation of fomepizole therapy, the endogenous ethylene glycol elimination half-life is expected to be less than 18 hours [48,49]. Thus, patients with a normal serum creatinine and arterial pH at the start of fomepizole therapy may forgo hemodialysis despite high serum ethylene glycol concentrations [48,95,114]. Although a similar strategy has been reported for a patient with combined methanol/isopropanol ingestion [130], the prolonged methanol elimination half-life (approximately 50 hours) after ADH inhibition [53,134] would favor hemodialysis when readily available and technically feasible [53]. Intermittent hemodialysis is preferred when available, especially for acidemic patients, because of the much higher elimination of the toxic acid metabolites [53]. During mass outbreaks, however, both continuous and intermittent hemodialysis have been utilized, with no reported significant differences of mortality rates between these two dialytic modalities [135]. Therefore, although intermittent hemodialysis is suggested as the most effective method to decrease serum alcohol levels and for removing organic acid anions [35], in the setting of limited resources, continuous hemodialysis should also be considered. Acid–base status, renal function, and serum ethylene glycol or methanol levels must be closely monitored for patients in whom hemodialysis is withheld [107].

**TABLE 99.6 Indications for Hemodialysis in Methanol or Ethylene Glycol Poisoning**

| Renal dysfunction as evidenced by increased serum creatinine concentration<sup>a</sup> |
| Severe metabolic acidosis (pH <7.25) with evidence of end-organ toxicity (abnormal renal function for ethylene glycol, visual toxicity for methanol) independent of |
Ethylene glycol clearance rates of 156 to 226 mL per minute (fractional excretion 43% to 92%; half-life 2.3 to 3.5 hours) can be expected during hemodialysis, as compared with renal clearance rates of 27.5 ± 4.1 mL per minute (fractional excretion 26% ± 9%) in patients with normal renal function, and clearance rates of 1 to 6 mL per minute in patients with renal dysfunction [48,136]. Glycolic acid is removed by hemodialysis, with a clearance of 105 to 170 mL per minute (half-life 2.5 hours) [37,40,43]. The hemodialysis elimination rate for methanol is 142 to 286 mL per minute; for formate, it is 148 to 203 mL per minute [7,54,63,84,137].

Hemodialysis should be continued until serum ethylene glycol or methanol levels are below 20 mg per dL (200 mg per liter) and acid–base derangements has been corrected [35,53,42,95]. The required duration of hemodialysis in hours can be estimated using the formula \[-V \ln (20/A)/0.06 \times k\], where \(V\) is total body water in liters, \(A\) is the initial alcohol concentration in mg per dL, and \(k\) is 57% of the dialyzer urea clearance in milliliters per minute at the observed blood flow rate [138–140]. More than one round of hemodialysis may be necessary for those with massive overdoses and for ethylene glycol–poisoned patients with renal failure.

Peritoneal dialysis is markedly inferior to hemodialysis because of its low clearance of alcohols and organic acid anions [35]. Continuous arteriovenous hemofiltration with dialysis has been used in a hemodynamically unstable patient, but is less efficient at toxin removal [141]. Sorbent-based hemodialysis systems were inadvertently shown to be ineffective for methanol removal because of rapid saturation of the sorbent cartridge [142] and charcoal cartridges saturate within a few hours [132].

Patients with ethylene glycol poisoning who have acute renal failure
may require hemodialysis for several months. Recovery of renal function is the expected course, although renal dysfunction may be permanent [37,42,83,90,128,143]. Full neurological recovery is possible even after prolonged coma and seizures. Transient cranial nerve palsies developing 4 to 18 days after ingestion have been reported in under- or untreated patients [71–73,136]. Bilateral basal ganglia and brainstem infarction can occur in severely ethylene glycol–poisoned patients [144].

Seizures, coma, and severe acidosis among patients with methanol poisoning portend a poor prognosis [56,145]. Cerebral edema is a common postmortem methanol toxicity finding [114]. The development of dilated, unresponsive pupils may indicate either severe optic nerve damage or cerebral edema [52]. Other neurologic sequelae include a parkinsonian-like syndrome, spasticity, transient resting tremor, cognitive defects, and paraplegia. Computed tomography, magnetic resonance imaging, and autopsy studies have documented frontal lobe and basal ganglia hemorrhages and infarcts, especially in the putamen [146,147]. Bilateral putaminal hemorrhage and/or insular subcortex white matter necrosis correlate with a poor clinical outcome following methanol toxicity. The etiology of these lesions remains uncertain, but they are likely due to the direct toxicity of methanol and/or its metabolites. These abnormalities usually occur among severely acidemic patients with delayed presentation or diagnosis.

Harvesting of organs for transplant is not precluded for patients who die from ethylene glycol or methanol poisoning. Several centers have reported successful experience with kidney, heart, lung, pancreatic β cell, and liver procurement from methanol-poisoned patients [127,148].
ISOPROPANOL

Isopropanol (isopropyl alcohol) is a clear, colorless, volatile liquid with a disagreeable taste and characteristic odor [149]. It is commonly available over the counter in 70% solutions of “rubbing alcohol,” but it is also used in cleaners, disinfectants, hand sanitizers, cosmetics, solvents, inks, and pharmaceuticals [150]. Because of its ready availability at an inexpensive price, abusers of alcohol often ingest isopropanol as an ethanol substitute. Cases of toxicity have been reported among children who were sponge bathed with the compound [151]. The NPDS reports that during 2014 the poison centers received 12,479 calls related to isopropanol exposures [36].

Isopropanol produces CNS depression, coma, and death from respiratory depression. In this respect, it has twice the potency of ethanol [152], a phenomenon attributed to its higher molecular weight [149] and possibly the CNS depressant effects of its metabolite, acetone. Depending on individual tolerance, serum concentrations of 150 mg per dL or greater may induce coma, and levels of 200 mg per dL or greater can be fatal in untreated patients, although lower concentrations may produce severe adverse effects [35,153].

The chemical properties and kinetics of isopropanol are summarized in Table 99.1. Oral absorption occurs quickly, and peak plasma concentrations can occur within 30 minutes [150]. Eighty percent of an absorbed dose is oxidized to acetone via ADH (Fig. 99.5) [149]. Acetone cannot undergo further oxidation to a carboxylic acid, however. Therefore, metabolic acidosis is not a feature of isopropanol toxicity unless respiratory depression with hypoxia or hypotension results in lactate production. Excretion of acetone and unchanged isopropanol (20% of an absorbed dose) is predominantly renal, with some excretion by respiratory, gastric, and salivary routes. Acetone can be detected in the urine within 3 hours of ingestion [154]. The elimination half-life of isopropanol can be as long as 5.8 hours for infants [155]. Serum acetone levels frequently remain elevated after isopropanol levels are undetectable because acetone is eliminated slowly, with a half-life of 10.8 to 31.0 hours. The contribution of acetone to the prolonged duration of CNS depression remains speculative [149].
Clinical Presentation

An “intoxicated” patient without acidemia, yet with positive serum or urinary ketones and a fruity breath odor, should be suspected of isopropanol intoxication. Initial signs and symptoms usually consist of mild intoxication followed by gastritis, abdominal pain, nausea, vomiting, and possibly hematemesis [149]. Hemorrhagic tracheobronchitis may occur. As CNS depression progresses, patients become ataxic, dysarthric, confused, stuporous, and comatose. Pupils are typically miotic, but mydriasis has been reported [149,156]. Respiratory depression and hypotension may occur with severe intoxication [157]. Because of the profound and prolonged cerebral depressive effects of isopropanol, comatose patients may develop compartment syndromes and rhabdomyolysis with myoglobinuria.

Many patients who ingest isopropanol are ethanol abusers who have a multitude of associated diseases, including chronic liver disease, pancreatitis, traumatic injuries, and chronic obstructive pulmonary disease, which may complicate the clinical picture.
Diagnostic Evaluation

Patients with known or suspected isopropanol poisoning should have quantitative isopropanol and acetone serum levels along with the laboratory studies noted for acute ethanol intoxication. The presence of high levels of acetone can interfere with older creatinine assays based on a colorimetric method, producing a falsely high creatinine value in the presence of a normal BUN [158]. In patients who may have also ingested other toxic alcohols, serum osmolality, ethanol, ethylene glycol, and methanol levels should also be obtained.

The differential diagnosis of isopropanol poisoning includes toxic and metabolic states in which ketonemia may develop, such as alcoholic, diabetic, and starvation ketoacidosis. Patients with these conditions have elevated acetoacetate, β-hydroxybutyrate, and acetone levels compared with the isolated acetonemia seen with isopropanol intoxication. Traces of isopropanol may be detected among patients with diabetic or AKA because of the back reduction of acetone to isopropanol [159]. Poisoning by salicylate, cyanide, and acetone itself (which is found in nail polish and super glue remover) and inborn errors of metabolism should also be considered in the differential diagnosis of unexplained ketosis. Some degree of metabolic acidosis is expected in most of these conditions, whereas it is absent in uncomplicated isopropanol or acetone poisoning cases.

Management

Treatment is similar to that described for acute ethanol intoxication. Airway management and evaluation for hemorrhagic gastritis are particularly important. IV fluids should contain glucose, and serum glucose levels should be periodically checked. Isopropanol and acetone are removed by hemodialysis, but such therapy is rarely indicated. Occasionally, patients with serum isopropanol concentration >200 mg per dL accompanied by hemodynamic instability despite IV fluids may benefit from hemodialysis [35,149]. Since acetone is less toxic than isopropanol, there is no indication for either fomepizole or ethanol therapy [130,150,160].

Most patients recover with appropriate airway management and treatment of complicating factors. CNS depression and volume depletion secondary to vomiting can cause hypotension [149]. Pulmonary edema and hemorrhage are common findings on autopsy and should be anticipated in severely ill patients.
**PROPYLENE GLYCOL**

Propylene glycol (1,2-propanediol) is commonly used as a solvent (e.g., in laundry stain removers), as an antifreeze, in hydraulic fluids, and as a diluent for a number of pharmaceuticals, including IV formulations of chlordiazepoxide, lorazepam, diazepam, etomidate, phenobarbital, pentobarbital, phenytoin, procainamide, nitroglycerin, and theophylline and topical silver sulfadiazine cream. Oral and dermal absorption is usually poor, but toxic amounts may be absorbed through abraded or burned skin [161]. Approximately one-half of a dose undergoes hepatic oxidation via ADH to lactate, and then to pyruvate and acetate. The rest is excreted unchanged in the urine [162].

Although oral doses of as much as 1 g per kg are essentially nontoxic, toxicity can occur following rapid or prolonged infusion of higher doses. Rapid IV infusion, as might occur during phenytoin loading, can cause prolonged PR and QRS duration, idioventricular rhythms, and cardiorespiratory depression and arrest [163]. Infusion of smaller doses has also precipitated cardiac standstill [164]. Propylene glycol, rather than phenytoin, is responsible for such toxicity [163]. Elderly patients, especially those with severe underlying cardiac disease, are at increased risk and should be infused with medications containing propylene glycol at rates slower than those usually recommended.

More commonly in the intensive care setting, frequent repeat IV dosing of medications containing propylene glycol can lead to accumulation of propylene glycol and its metabolites, resulting in seizures and decreased level of consciousness. Propylene glycol toxicity has been described following extremely high doses of diazepam for ethanol withdrawal, massive ingestion of products containing propylene glycol, or the chronic dermal absorption of silver sulfadiazine through damaged skin [165–167]. On laboratory testing, an osmolar gap and high serum lactate concentrations are expected. Propylene glycol can be mistaken for ethylene glycol on gas chromatography [168].

Management of this iatrogenic condition consists of immediately stopping IV infusion or dermal application and supportive therapy. Although theoretically fomepizole may be beneficial to block the metabolism of propylene glycol, this therapy cannot be universally recommended at this time without more information, including information on the relative toxicity of the parent compound to its metabolites [35,169]. Hemodialysis and continuous venovenous hemofiltration have reportedly been used to treat patients with propylene glycol toxicity, especially in the setting of renal failure, high blood concentrations, or severe metabolic acidosis [35,170,171].
Diethylene glycol (2,2’-dihydroxydiethyl ether, ethylene diglycol, 2,2’-oxydiethanol, 3-oxapentane-1,5-diol; DEG) is a viscous and sweet-tasting liquid found in resins, antifreeze, brake fluids, cosmetics, wallpaper strippers, inks, lubricants, liquid heating/cooking fuels, plasticizers, adhesives, paper, and packaging materials [172,173]. Over the years, diethylene glycol has resulted in tragic outbreaks of renal failure and death following its substitution for propylene glycol in medications [174,175]. Unlike propylene glycol, diethylene glycol can cause acute renal failure, elevated liver enzymes, encephalopathy, and delayed neurologic toxicity. Since the first reported outbreak that occurred in the United States in 1937, there have been other outbreaks worldwide, including South Africa (1969), Spain (1985), India (1986 and 1998), Nigeria (1990 and 2008), Bangladesh (1990 to 1992), Argentina (1992), Haiti (1996), Panama (2006), and China (2006). These outbreaks often involved medications, such as acetaminophen, cough syrup, or teething syrup, ingested by children. The number of identified deaths during each outbreak ranged from 5 to 236. The median toxic dose is estimated to be approximately 0.14 mg per kg [35,176].

Following diethylene glycol ingestion, patients may present with gastrointestinal symptoms, inebriation, CNS depression, acidosis, and acute renal failure. Interestingly, additional neurologic symptoms may develop up to several weeks after the ingestion and include cranial nerve palsy, peripheral neuropathy, dysphonia, lethargy, mental status changes, quadriplegia, and seizures [174,177]. Metabolism of diethylene glycol via hepatic ADH leads to 2-hydroxyethoxyacetic acid (HEAA) [173]. Although HEAA is believed to be the primary toxic metabolite, the parent glycol itself may also be directly toxic. Although the name suggests the potential to be metabolized to two ethylene glycol molecules, this does not occur in vivo [173]. Survivors with renal failure tend to remain dialysis dependent, and the degree of renal injury may be a predictor of delayed neurologic sequelae. Treatment is similar to ethylene glycol, including ADH inhibition using fomepizole or ethanol, extracorporeal elimination, and supportive care [35]. Fomepizole alone without hemodialysis, however, is not recommended given the uncertain toxicity of the diethylene glycol itself, the frequency of associated renal failure, and the theoretical dialyzability of diethylene glycol and HEAA [35,113,173,174]. Case reports exist of successful treatment of pediatric patients with fomepizole for diethylene glycol toxicity using the same dosing regimen as adults [35,116].

Chapter 100

Amphetamines
MICHAEL C. BEUHLER

INTRODUCTION

The term “amphetamine” includes a wide range of amine compounds with sympathetic-like effects. The simplest member of this group is amphetamine, but hundreds of related molecules have similar clinical effects. This chapter will focus on the more important and commonly used licit and illicit members of this group.

Amphetamine and methamphetamine are the most well-known members of this class. Amphetamine or alpha-methyl phenylethylamine was first synthesized over 125 years ago, and it was widely used by many (including the United States military) as the stimulant Benzedrine, beginning in the 1930s. Restricting use to prescription only has decreased the prevalence slightly, but amphetamines continue to be used for both licit (attention deficit hyperactivity disorder [ADHD], narcolepsy, and weight loss) and illicit reasons. Currently, Adderall (a mixture of l and d amphetamine) and Vyvanse (lisdexamfetamine; hydrolyzed to d-amphetamine) are two commonly used medicinal amphetamine preparations.

Methamphetamine (or N-methyl amphetamine) is available for prescription use in generic form and under the trade name Desoxyn(R) for ADHD and obesity. The illicit abuse of methamphetamine is undergoing a surge in the US and worldwide popularity. One reason for its popularity over amphetamine is its longer duration of action. Another reason is that the Drug Enforcement Agency has taken actions to limit the availability of precursor compounds for the synthesis of amphetamine, including the unrelated removal of phenylpropanolamine from the market. Finally, synthesis can be conducted by individuals without training using materials that are easily obtainable, potentially resulting in a relatively pure product.

Several other medicinal compounds have clinical effects similar to
amphetamines; a select few are discussed here. Methylphenidate (Ritalin(R)) is commonly used in children for ADHD and is occasionally abused. Phenylpropanolamine (Dexatrim(R)) was used more extensively in the past as a decongestant and weight loss agent; in 2005, the Federal Drug Administration (FDA) deemed phenylpropanolamine unsafe owing to concerns for increased stroke risk, removing it from the human market. Ephedrine has been used extensively in the past in herbal weight loss/energy preparations as well as a decongestant in cough/cold preparations; but in 2004, the FDA prohibited the sale of dietary supplements containing ephedra (ephedrine and pseudoephedrine) over safety concerns. In addition, in 2006, requirements regulating the sale of ephedrine were enacted in an attempt to limit its diversion for methamphetamine synthesis. Phentermine is an amphetamine derivative that is used for appetite suppression. Selegiline is an amphetamine derivative with selective monoamine oxidase inhibitor (MAOI)-B effects that is metabolized to l-methamphetamine. Propylhexedrine (Benzedrex(R) nasal inhaler), although not a true amphetamine, has sympathomimetic and vasoconstrictor properties and is occasionally abused.

Some amphetamine analogs with aromatic ring substitutions have direct affinity for serotonin receptors as well as increased inhibition of serotonin uptake, thereby exerting both sympathomimetic and serotonergic effects manifested by hallucinatory properties. One of the more popular compounds in this group is 3,4-methylenedioxymethamphetamine (MDMA or Ecstasy). Other similar ring-substituted amphetamine compounds include 3,4-methylenedioxyamphetamine (MDA), 3,4-methylenedioxy-N-ethylamphetamine (MDEA or Eve), 2,5-dimethoxy-4-bromo-phenethylamine (2-CB; not strictly an amphetamine), para-methoxyamphetamine (PMA), 2,5-dimethoxy-4-methyl-amphetamine (DOM), and 2,5-dimethoxy-4-bromo-amphetamine (DOB; also the chlorine and iodine derivatives DOC and DOI exist). The 2,5-dimethoxy halogenated amphetamine derivatives (DOB, DOC, DOI) are common substitutions for lysergic acid diethylamide (LSD) found on blotter paper in the United States [1].

There has been a recent surge in the availability and abuse of synthetic cathinones; these compounds all have a β-keto phenylalkylamine group. Bupropion is a cathinone derivative used therapeutically for depression and smoking cessation that has sympathomimetic properties; most notably for causing seizures and ventricular dysrhythmias in supratherapeutic doses. The illicit cathinones are also referred to as “bath salts” and represent a large number of compounds such as methylone, α-pyrrolidinopentiophenone (PVP), and 3,4-methylenedioxyxypyrovalerone (MDPV) [2]. Although many of these are Schedule I Controlled
Substances (i.e., high abuse potential with no recognized therapeutic indications), there is a constant flux of new derivatives. Because of the constant change in which compounds are observed, limited clinical experience with specific compounds and chapter space restrictions, the synthetic cathinones will not be specifically discussed, although notable class cathinone effects will be covered. However, the principles in this chapter can be applied to treating exposures to these compounds because they share many of the clinical effects of amphetamines [3].

Recent increases in clandestine methamphetamine production facilities (“meth labs”) have resulted in concern for environmental contamination and bystander toxicity from laboratory chemicals. The vast majority of illicit amphetamine laboratories currently produce methamphetamine by reductive dehydroxylation of ephedrine or pseudoephedrine. Methamphetamine laboratories are often discovered after a chemical mishap or explosion, and health risks from these chemicals include respiratory irritation and caustic injury.

Alternatively, methcathinone is a potent, occasionally used cathinone produced from the oxidation of ephedrine in amateur labs, instead of the usual reduction to methamphetamine; toxicity from it is similar to the amphetamines except that cases of Parkinson-like neurotoxicity from intravenous (IV) exposure to the manganese in the impure product have been reported.

Methamphetamine is synthesized most commonly by two methods. The probably more dangerous one is the Birch or “Nazi” method, which utilizes lithium metal as the reducing agent dissolved in either anhydrous ammonia or a modified method using ammonium nitrate and solvent in a bottle (“shake and bake”). The other method is the hydriodic acid method, which usually utilizes red phosphorus and iodine.

Depending upon the illicit amphetamine purchased, there is a chance that it will contain one or more contaminants, or possibly be substituted by another drug. Street purchased methamphetamine tends to be of better purity than cocaine, whereas MDMA is very commonly substituted or combined with other psychoactive substances. “Crystal Meth” is a nearly pure crystalline form of methamphetamine. The exact “contaminants” or other chemicals present in street purchased amphetamines are highly variable, based on drug, year, and location. Previously reported substitutions include acetaminophen, anesthetics (benzocaine, lidocaine, and procaine), cocaine, caffeine, ephedrine, ketamine, lead (rare), talc, phencyclidine, piperazine compounds (benzylpiperazine and others), phenylpropanolamine, pseudoephedrine, strychnine, and quinine [4]. Depending on the quantity of the adulterant, it may contribute to the effect or toxicity of the sympathomimetic drugs.
Occasionally, an individual will ingest an amphetamine while it is wrapped in plastic or other nonpermeable material. Body *packers*, or “mules,” are people who transport large quantities of specially prepared drug packets in their gastrointestinal (GI) tract. Each packet usually contains drugs in sufficient quantity and purity to cause life-threatening toxicity if rupture occurs. Body *stuffers* are people who quickly swallow (“stuff”) drug-containing packets in an attempt to get rid of evidence and avoid arrest by the police. These packets are usually poorly prepared and are at increased risk of leakage and rupture, but often contain far less drug than a packet from a body packer. Body *pushers* are people that hide drug packets in their vagina or rectum; serious illness has been observed in some cases. Rarely, individuals will ingest a plastic bag containing a drug with holes or a corner of the bag cut off in an attempt to produce a sustained release effect (“parachuting”) [5].
Amphetamine and methamphetamine are similar in their pharmacokinetic properties and have similar physiologic effects in humans [6]. They do not have significant direct effects at adrenergic or dopamine receptors; rather, their effects are mediated by an increase in the concentration of synaptic dopamine and, to a lesser extent, serotonin, and norepinephrine. This increase in biogenic amines occurs by several mechanisms. Amphetamine and methamphetamine enter the presynaptic cytoplasm through both passive diffusion and active uptake by biogenic amine uptake transporters. Amphetamine moves into the synaptic vesicles by diffusion and by the vesicular monoamine transporters (VMAT), subsequently causing release of stored dopamine and norepinephrine, most likely by raising the pH and effecting VMAT. This increases the cytosolic levels of these biogenic amines, resulting in increased synaptic levels due to reverse transport activity by the amine transporters, especially the dopamine transporter. Part of the mechanism of action of amphetamines’ raising synaptic levels is also caused by competitive inhibition of biogenic amine reuptake from the synapse into the presynaptic terminal. Finally, some amphetamines have MAOI activity, which inhibits the breakdown of dopamine, serotonin, and norepinephrine, with a few (PMA for example) having significant MAOI activity [7,8].

The mechanism of action of MDMA toxicity includes a direct effect at some serotonin receptors, as well as some of the indirect effects from serotonin release, as described above. Additionally, human and animal studies have shown that MDMA produces a dose-related depletion of serotonin and serotonin transporter activity, as well as serotonergic neuronal degeneration [9]. Methamphetamine causes dopamine and serotonergic neuronal toxicity as well as a decrease in dopamine, VMAT, and serotonin transporter activity in the brain, at least in part by free radical injury [10,11].

Peak plasma concentrations of methamphetamine are reported within 4 hours for an intranasal (insufflated, snorted) dose, within 2 to 3 hours for a smoked (inhaled) dose, and nearly immediately for an IV dose [12]; however, levels do not correlate with the degree of clinical toxicity [13]. Methamphetamine and amphetamine have a $l$- and $d$-isomer; the $d$ form is more potent in causing pleasurable central nervous system (CNS) stimulation and persistent cardiovascular activation than the $l$ form [14]. Most abused methamphetamine is the $d$ isomer, having been synthesized from ephedrine or pseudoephedrine. However, the $d$ form of methamphetamine has a shorter half-life (10 to 11 hours) than the $l$ form.
(13 to 15 hours) [14]. The majority of methamphetamine is either eliminated unchanged, $N$-demethylated to amphetamine (active) or hydroxylated to $p$-hydroxymethamphetamine (active) with contribution from CYP2D6 [15]. The α-carbon on the ethyl side chain protects it against MAO degradation. Amphetamine undergoes a similar metabolism, except that it is deaminated to an inactive metabolite as well as hydroxylated to $p$-hydroxyamphetamine (active). Excretion of both is increased in acidic urine, but this fact has limited clinical utility as the risks of urinary acidification outweigh potential benefits. The urine drug screen usually remains positive for at least 24 hours in high-dose, chronic abusers. The serotonergic amphetamine and amphetamine-like compounds (MDMA, PMA, 2-CB) are not metabolized to amphetamine or methamphetamine and have a variable, unpredictable effect on the typical amphetamine urine drug screen.
CLINICAL PRESENTATION

Methamphetamine toxicity has been reported following ingestion, inhalation, insufflation, rectal, subcutaneous, intramuscular, or intravenous exposure [16]. The onset and duration of methamphetamine toxicity depends on factors such as dose, route of exposure, individual tolerance, pattern of use, ambient temperature, and crowding/stimulation level. Most people develop signs and symptoms within a few minutes of parenteral drug use, whereas signs and symptoms may be delayed for hours or days after ingestion with body packers and body stuffers. In most patients, the majority of sympathomimetic effects are expected to resolve within 24 to 36 hours postexposure [16]. Life-threatening toxicity is more common in drug abusers and in people who overdose with suicidal intent, and it can also occur in body packers and body stuffers.

Methamphetamine toxicity usually results in a group of signs and symptoms known as the “sympathomimetic toxidrome,” including hypertension, tachycardia, tachypnea, hyperthermia, diaphoresis, mydriasis, hyperactive bowel sounds, agitation, anxiety, and toxic psychosis. This pattern of symptoms is seen in other members of the amphetamine group, as well as the cathinones and other sympathomimetics such as cocaine and to some extent caffeine; but this pattern of symptoms can be variable depending on the sympathomimetic agent involved. For example, phenylpropanolamine has peripheral alpha vasoconstrictive effects that can result in a reflex bradycardia.

Airway and breathing abnormalities are uncommon with ingestion. Transient cough, pleuritic chest pain, and shortness of breath are common after insufflation or smoking. People presenting from illicit drug laboratory fires may have thermal injury to their oropharynx or upper airway, specific toxic issues from drug laboratory fires are extremely uncommon. Insufflation or smoking methamphetamine may result in bronchospasm, pneumothorax, pneumomediastinum, pneumonitis, and noncardiogenic pulmonary edema. Noncardiogenic pulmonary edema and acute respiratory distress syndrome may be associated with multisystem organ failure. Tachypnea is common secondary to agitation or metabolic acidosis. Hypoventilation is rare but may occur secondary to intracranial pathology or the end stage of multisystem organ failure.

Many of the adverse cardiovascular effects result from increases in peripheral catecholamines, which result in a mismatch of oxygen consumption and delivery; there may be a direct cardiotoxic effect of methamphetamine as well. Palpitations and chest pain are common complaints. Acute myocardial infarction due to vasospasm, plaque
rupture, and/or thrombosis can occur [17]. Life-threatening atrial or ventricular dysrhythmias, sudden death, and aortic dissection have been reported, with potential synergy if cocaine is also present [17]. Coronary artery disease and cardiomyopathy have been reported with chronic amphetamine abuse [14,18–20]. Peripheral vascular ischemia can result from oral sympathomimetic abuse but is uncommon; however, inadvertent intra-arterial injections can result in significant injury. Hypotension is unusual but may be secondary to dehydration, myocardial depression, intestinal ischemia, or sepsis.

Several important findings may be apparent on the head-eyes-ears-nose-throat exam. Mydriasis is common, and various forms of nystagmus have been reported. Patients who abuse and binge on sympathomimetic agents are often dehydrated and have dry mucous membranes; this can complicate the diagnosis by incorrectly suggesting anticholinergic toxicity. Nasal mucosal abnormalities, including nasal septal perforations, are well reported in patients who chronically insufflate cocaine and are possible with insufflation of other sympathomimetics. An increase in dental pathology has been noted in users of methamphetamine, manifested by a distinctive pattern of caries on the buccal smooth surfaces of the posterior teeth and the interproximal surfaces of the anterior teeth. The teeth may be loose, rotting, or crumbling, and are usually beyond salvage. The pathology of these changes is uncertain, but is believed to result from a combination of decrease in salivation (xerostomia) along with increased ingestion of sugar- and acid-containing sodas, poor hygiene, poor nutrition, localized vasospasm, and bruxism, a side effect especially seen with MDMA [21].

Central nervous system effects are the reason for abuse as well as often the reason for medical care. Methamphetamine produces a euphoric and anorexic effect, with smoked and injected administration producing a greater “rush.” The most common presenting symptoms include agitation and altered mental status; other symptoms include headache, hyperactivity, toxic psychosis, loss of consciousness, focal neurologic deficits, or seizures [16,22]. Hyperthermia may be more common and worse in patients with uncontrolled psychomotor agitation, especially when patients are physically but not chemically restrained. The cathinones or “bath salts” are notorious for causing extreme agitation, hyperthermia, and rapid demise. Deaths due to excited delirium from amphetamines and cathinones have been reported. Altered mental status may be secondary to hypoglycemia or an acute intracranial process. Headache may be secondary to intracranial or subarachnoid hemorrhage.
Focal neurologic deficit may be secondary to cerebral ischemia or infarction, vasospasm, or direct injection trauma. On arteriography, multiple occlusions or “beading” of the arteries has been observed; this is thought to represent some combination of local vasospasm or vasculitis [23,24]. Seizures may occur in association with and independent of intracranial hemorrhage or cerebral infarction. Prolonged methamphetamine (and probably MDMA) use may lead to cognitive decline represented by attention and memory changes [11].

Some abusers develop stereotyped, compulsive behavior such as cleaning or buttoning shirts; in some cases, it has been observed that addicts compulsively disassemble appliances, usually without reassembly. Psychosis from amphetamines can present as paranoid delusions and perceptual disturbances; these may persist long after the drug has been stopped and can result in homicidal or self-destructive behavior [16,25,26]. Severe and prolonged psychosis following cathinones or “bath salts” abuse may be more common than from amphetamines. After binge use of amphetamines, patients may develop a withdrawal pattern of symptoms consisting of generalized fatigue, dysphoria, decreased level of consciousness, and profound lethargy.

One occasionally sees choreiform, ballistic, bruxism, torticollis, or athetoid involuntary movements with amphetamine, methamphetamine, and cathinone abuse [27]. These movements can be fast or slow, and they can involve the facial, extremity, or trunk muscles. Ataxia may result if the trunk or limb movements are severe enough. These movements usually begin after prolonged abuse of amphetamine or methamphetamine and may worsen or reoccur with additional drug abuse. Usually, the symptoms resolve over several hours to a week following abstinence. However, they may only diminish in magnitude and persist for months or, rarely, even years. The movements may be diminished with voluntary motor activity or during sleep. The mechanism for these movements is not well understood, and may involve a disruption of the normal dopamine neurotransmitter system [28].

Abdominal findings may include increased bowel sounds, bowel obstruction from body packing, and abdominal pain due to intestinal ischemia or bowel perforation [29]. Rhabdomyolysis can result from psychomotor agitation and seizures. Hyperthermia and multisystem organ failure may result in coagulopathy and disseminated intravascular coagulation (DIC). Dehydration, increased anion gap metabolic acidosis associated with increased lactate, and hypokalemia are common in patients with significant sympathomimetic toxicity. Urinary retention has been reported from amphetamine toxicity. Acute tubular necrosis may occur secondary to hyperthermia, hypovolemia, hypotension, and rhabdomyolysis.

Diaphoresis with either warm or cool skin is common. Scarring and
hyperpigmentation (“track marks”) in areas above veins suggest chronic intravenous drug use. Subcutaneous injection of the drug (“skin popping”) can result in scabs, circular scars, and lesions in a variety of areas. Additional excoriations and rashes can result from skin picking and scratching. Abscesses and infection are common.

Medical complications from drug abuse include endocarditis, infectious hepatitis, human immunodeficiency virus infection (HIV), cellulitis, septic emboli, abscesses, tetanus, or wound botulism. Methamphetamine abuse is associated with an increased risk of HIV infection because of both increase in risk-taking behavior (IVDA, unprotected intercourse, untreated STDs) and probable enhancement of HIV infectivity [30].

In general, the toxicity observed in patients using methamphetamine is attributable to the drug and not to any adulterants. Adulterants are not usually present in large enough quantities, and methamphetamine is relatively pure and sufficiently toxic in its own right. However, some important exceptions should be noted. The addition of benzocaine has caused methemoglobinemia [31]. Intra-arterial injection of a drug may cause injury, possibly potentiated by any talc present. Talc pulmonary emboli have been reported as well, which probably contribute to pulmonary hypertension. Lastly, substitution is more of a problem with the ring-modified amphetamines (MDMA); the real substance present in the street purchased product is likely to be contaminated with or entirely comprised of something else such as a pipеразине (e.g., benзилpiperazine), caffeine, methamphetamine, cathinone (e.g., methylone), or some other substituted amphetamine such as the very dangerous PMA.

In addition to having some sympathomimetic qualities, nearly all of the ring-substituted amphetamines (e.g., MDMA and DOM) also have hallucinogenic properties likely owing to their direct and indirect effect at serotonin receptors. The route of abuse for MDMA is usually ingestion. MDA, an analog of MDMA, has similar effects to those of MDMA. Serious autonomic reactions include many of the sympathomimetic symptoms discussed earlier as well as seizures, rigidity, dysrhythmias, and profound hyperthermia with grave consequences (rhabdomyolysis, renal failure, DIC) [32]. Given the increased serotonin levels produced, at least part of this toxicity should be characterized as serotonin syndrome.

Some of the ring-substituted amphetamines have specific toxicities. There are several reports of hepatotoxicity resulting in hepatomegaly, jaundice, and death caused by MDMA that did not stem from hyperthermia or shock liver; this probably resulted from an immunologic component [32,33]. Hyperthermia is more common with the ring-substituted amphetamines, likely from contribution from serotonin toxicity and possibly from mitochondrial uncoupling [34]. Hyponatremia resulting in altered mental status, coma, seizures, cerebral edema, and
death is also sometimes seen following MDMA use. This probably results from some combination of inappropriate antidiuretic hormone secretion (SIADH) and from excessive water drinking. This SIADH may be more commonly observed in young women using MDMA as an inappropriately large number of cases are reported in this age/gender group. The observed clinical toxicity from PMA (street name “death”) includes hyperthermia, hypoglycemia, hyperkalemia, and EKG changes. PMA effects are similar to MDMA but may be more severe because of the steep dose–response curve for elevating brain serotonin levels and significant MAOI activity [7,35]. PMA exposures are often unintentional, with accidental or purposeful substitution for MDMA causing most exposure, and the long onset time sometimes results in users taking multiple doses. DOB is highly potent, enough so that a dose (2 to 5 mg) can be found on a small piece of paper possibly being sold as LSD. Large doses of DOB have been reported to result in significant vasospasm, resulting in seizures, gangrenous amputations, and deaths [36].
Patients with amphetamine toxicity (sympathomimetic toxicity) should have frequent vital sign determinations including core or rectal temperature measurement, intravenous access, and continuous cardiac monitoring. Patients with abnormal vital signs or mental status should have an electrocardiogram, complete blood cell count, electrolyte, blood urea nitrogen, creatinine, glucose, and arterial blood gas determinations. Patients with chest pain, dysrhythmias, or persistent pulse or blood pressure abnormalities should be evaluated for acute coronary or vascular syndromes. Patients with prolonged immobilization, uncontrolled psychomotor agitation, or hyperthermia should have serial CPKs to evaluate for rhabdomyolysis and consider the possibility of compartment syndrome. Those that either have or have had significant hyperthermia or shock should also have liver injury and function tests (lactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, and coagulation profile) to screen for multisystem organ failure and DIC.

Several imaging studies may be warranted for an amphetamine toxic patient, depending on his or her clinical presentation. Those with respiratory symptoms or chest pain should have a chest radiograph and potentially a chest computed tomography (CT) when there is concern for aortic dissection. Patients with headache or seizures should be evaluated for intracranial hemorrhage with CT of the brain. Those with continued suspicion for subarachnoid hemorrhage with a negative CT scan should also have a lumbar puncture [23]. Plain and oral contrast abdominal radiographs may be helpful in detecting drug-containing packets in the GI tract of body packers, but their sensitivity is quite low for stuffers. Experience with abdominal CT and abdominal ultrasound for detection of stuffer packets is limited. A negative imaging study cannot definitively rule out drug packets in the GI tract.

The results of toxicology screening for most drugs of abuse rarely contribute to or alter patient management. However, in the case of sympathomimetic toxicity, the urine drug screen is reasonably sensitive to the recent use of methamphetamine/amphetamine as well as cocaine and can assist in differentiating these syndromes, which can be important in management. If toxicology drug screening is essential, health care providers should contact their clinical laboratory to determine included substances as well as causes of false-positive and false-negative results. For example, the ability of immunologically based amphetamine drug screens to detect MDMA (or similar ring-substituted amphetamines) is highly variable, but specific immunologically based MDMA drug screens
are available. Detection of the cathinones requires special specimen handling and testing.

A positive drug screen can confirm the presence of amphetamine or a similar structured drug, whereas a negative drug screen is nondiagnostic. For amphetamines, the screen is typically reasonably sensitive for use within the last few days, but has limited specificity. A sampling of some common substances that may cause a positive amphetamine screen are bupropion, chloroquine, clobenzorex, ephedrine, methylphenidate, phenelzine, phentermine, phenylpropanolamine, pseudoephedrine, selegiline, tranylcypromine, trazodone, and Vicks(R) inhaler [37]. One should remember that if the result of a toxicology screen is to be used for forensic purposes, the chain of custody should be maintained, and results will need to be confirmed using a more rigorous analytical method such as gas chromatography/mass spectrometry.

Toxicologic and nontoxicologic conditions that may have a similar presentation or that present concomitantly (Table 100.1) should be evaluated for and excluded. A serum lactate level may be helpful for patients with increased anion gap metabolic acidosis of unclear origin. An elevated lactate level would be expected for patients with compromised tissue perfusion (e.g., occurring with shock and intestinal or limb ischemia), for those with hypermetabolic states in which metabolic demands exceed available substrates, or for those with cellular dysfunction in whom normal substrates cannot be used. Other causes of increased anion gap metabolic acidosis (e.g., ethylene glycol, methanol, iron, and salicylate) should be investigated when the lactate level is normal or near normal. The possibility of concomitant poisoning with by-products or impurities related to the illicit synthesis of methamphetamine (e.g., phenethylamine derivatives, caffeine, ephedrine, mercury, strychnine, or lead) would be rare, but should also be considered.

MANAGEMENT

Patients who present with life-threatening effects from amphetamine toxicity or those that are at increased risk for developing them (such as a packer) should be managed in an intensive care unit (Table 100.2). The overall approach to these patients is aggressive supportive care with supplemental oxygen, sedation, fluid administration, prevention and treatment of hyperthermia, and close monitoring while addressing the specific myriad complications that can occur.

The hemodynamic effects of amphetamines are primarily caused by release of catecholamines and not by a direct effect at receptors. Mild sinus tachycardia and hypertension not associated with psychomotor agitation or evidence of end-organ damage usually do not require pharmacologic treatment. Treatment of psychomotor agitation utilizing occasionally large benzodiazepine doses (e.g., 100 mg of diazepam or its equivalent over 30 minutes with appropriate airway monitoring) will often result in improvement or resolution of tachycardia and hypertension. If sufficient benzodiazepines do not provide adequate improvement, rate-related cardiac ischemia may be treated with a β-blocker, preferably a short-acting and easily titratable agent such as
esmolol, or a calcium channel blocker, being cautious to exclude cocaine toxicity if a β-blocker is being used. Patients with life-threatening dysrhythmias who are hemodynamically unstable should be cardioverted or defibrillated. However in the author’s experience interventions specifically directed at reducing the heart rate have occasionally precipitated cardiovascular collapse. Persistent hypertension, especially if there is evidence of end-organ damage or hyperthermia, should be treated with benzodiazepines as well as phentolamine, nitroprusside, or nitroglycerin with careful dose titration.

Patients presenting with chest pain should be evaluated for acute coronary syndromes and managed accordingly [20]. Thrombolytic therapy or procedural coronary intervention may be indicated as per current guidelines. In these circumstances, cardiology consultation is recommended, especially since coronary vasospasm is a possibility. Other important potential causes of chest pain such as pneumothorax, pneumomediastinum, infection, septic emboli, and aortic dissection should be ruled out.

Hypotension should be treated with fluids and assessed for comorbid potential life-threatening conditions such as dysrhythmias, acute coronary syndromes, pneumothorax, aortic dissection, hyperkalemia, GI hemorrhage, and sepsis. Persistent symptomatic hypotension that is refractory to fluids necessitates treatment with a direct acting vasopressor such as norepinephrine, epinephrine, or phenylephrine. At times, the choice and dose of vasopressor should be guided by their different pharmacological properties as well as potentially pulmonary artery catheter hemodynamic monitoring or bedside ultrasound.

Management of bronchospasm should include nebulized β₂ agonists (such as albuterol) and anticholinergic agents (such as ipratropium bromide). Noncardiogenic pulmonary edema and acute respiratory distress syndrome should be managed according to current guidelines. The benefit of corticosteroids in patients with sympathomimetic-induced bronchospasm, pneumonitis, and noncardiogenic pulmonary edema has not been well studied, but may be considered in patients with severe or persistent symptoms. Occasionally, pneumomediastinum and pneumothorax following smoking methamphetamine is observed. Patients with pneumothorax may require tube thoracostomy depending on the size of the pneumothorax. Evaluation for a pneumomediastinum usually involves a nonbarium oral contrast imaging study to rule out esophageal perforation, but, surprisingly, these commonly have a completely benign course.

The initial management of a patient with an altered mental status includes assessing and treating all readily reversible causes such as hypoxia, hypoglycemia, electrolyte abnormalities (especially hyponatremia), opioid toxicity, and thiamine deficiency. Imaging studies
of the head should be performed on patients with persistent altered mental status, potentially followed by lumbar puncture if indicated. Mild agitation or anxiety may be treated with oral benzodiazepines. Psychomotor agitation that poses a danger to the patient or others requires more aggressive sedation. Incremental doses of intravenous benzodiazepine should be used to achieve the desired effect. The use of antipsychotics for controlling agitation should be as an adjunctive therapy and not as the primary means of control, but does appear to be safe and efficacious in adult and pediatric populations [16,38,39]. One should recognize the other clinical precautions that accompany the use of the antipsychotic drug class (e.g., EKG changes and neuroleptic malignant syndrome). If agitation is severe, more aggressive measures such as sedation, intubation, and paralysis may be required to protect the patient and the staff. Restraints should be used only during the relatively short time of gaining control of the agitation using pharmaceutical methods, as the restrained agitated patient is at risk for several adverse outcomes, including sudden death. Deaths from excited delirium occur quickly, and close cardiac and core temperature monitoring are essential.

Patients presenting with seizures should be treated with incremental doses of intravenous benzodiazepines. If seizures are not rapidly controlled, intravenous propofol (being watchful for hypotension) or phenobarbital is indicated usually along with intubation to secure the airway. The role of phenytoin is limited in the patient with toxin induced seizures and probably should be avoided. Seizures refractory to sedative–hypnotic drugs should be managed in consultation with an experienced neurologist with continuous electroencephalogram monitoring. The workup of seizures should include a CT scan and potentially lumbar puncture to evaluate for potential physical causes. Patients with intracranial hemorrhage or cerebral infarction should have neurosurgery consultation. As the etiology of the “beading” seen on angiography is uncertain, the role of calcium channel blockers (e.g., nimodipine) and/or steroids for such patients is equally uncertain.

Patients with peripheral vascular ischemia should be managed in conjunction with a vascular service. Intra-arterial administration of α-adrenergic receptor antagonists such as phentolamine may relieve localized arterial vasospasm. If multiple areas of vasospasm are observed, there may be a role for intravenous nitroprusside with caution not to lower systemic blood pressure significantly. This adverse effect may be observed more typically with some of the substituted hallucinogenic amphetamines such as DOB [36]. Accidental intra-arterial injection during intravenous abuse may lead to significant tissue destruction through emboli (e.g., talc and the other cutting agents), thrombosis, and vasoconstriction. There is no consensus regarding managing these patients, although adequate fluid resuscitation, acetylsalicylate, and
heparin appear to be reasonable; other interventions that have been used for intra-arterial injection accidents with heroin include intra-arterial phentolamine, thrombolytics, and systemic steroids (dexamethasone).

Core temperature approaching or more than 104°F (40°C) should be aggressively managed, as the risk for multisystem organ failure rises exponentially with the temperature. One should undress the patient, initiate active cooling measures, and continuously monitor the patient’s core temperature. Active cooling techniques include spraying the patient with cool water, draping with cold water–soaked sheets along with the use of large fans for evaporation, ice packs in the axilla and groin, or a cooling blanket placed under the patient while utilizing evaporative cooling from above. Active cooling should be terminated when the patient’s core temperature approaches 101°F (38.3°C). Benzodiazepines are useful for decreasing motor agitation or seizure activity contributing to the hyperthermia. Paralysis and intubation would be a last resort in the treatment of persistent rigidity associated with hyperthermia. Antipyretics (e.g., acetaminophen, aspirin, nonsteroidal anti-inflammatory drugs) are not useful, and there is limited evidence that dantrolene, bromocriptine, or amantadine enhances the cooling process in these patients with life-threatening hyperthermia.

Fluid management should address any electrolyte and acid–base abnormalities and dehydration. Management of rhabdomyolysis should include generous intravenous crystalloid fluids to maintain urine output of at least 2 to 3 mL/kg/h to minimize the risk of acute tubular necrosis. The role of alkalinizing the urine to provide renal protection from rhabdomyolysis is controversial, but may be performed as desired. Because serum myoglobin levels are not usually rapidly available, serum CPK may be monitored instead. Although no longer recommended for amphetamine toxicity, urinary acidification would increase the urinary excretion of amphetamine, but the risks outweigh the potential benefits.

The serotonergic amphetamines MDMA and related compounds can cause significant serotonergic toxicity when combined with other pharmaceuticals that have serotonin effects such as selective serotonin reuptake inhibitors, MAOIs, and cocaine. Differentiating the degree of concomitant serotonin toxicity can be difficult, but the physical examination findings of myoclonus and hyperreflexia with the lower extremity reflexes more pronounced than the upper extremity reflexes would be suggestive of serotonin toxicity. Treatment involves benzodiazepines and supportive care, although cyproheptadine may be of some benefit. An adult dose of cyproheptadine for serotonin toxicity is 8
mg orally every 6 to 8 hours to a maximum of 32 mg per day. The hyponatremia arising from SIADH should be treated with water restriction and may require hypertonic 3% normal saline. These fluid requirements should be balanced with other fluid issues such as the possible presence of rhabdomyolysis.

The involuntary abnormal choreiform and athetoid movements following abuse may be the reason for presentation and can be a source of great anxiety for the patient. When the symptom onset is rapid and not present for a long period of time, antipsychotics such as haloperidol may be effective [27]. When the involuntary movements have lasted for a long time (e.g., days to weeks), antipsychotics may be less effective. Sedatives have been observed to increase the movements in some patients. There has been some success in alleviating symptoms using centrally acting antimuscarinic drugs (e.g., benztropine) [28].

No treatment consensus is available for the management of asymptomatic body stuffers. Sometimes, individuals claim to have ingested drug packets in an attempt to avoid going to jail, a technique that often works in the short term. The packet count or the amount of drugs in the packet is usually unreliable. Even when bags or packets are ingested, they are rarely seen on imaging studies. An abdominal CT scan is more reliable than plain abdominal imaging, but false-negatives do occur. GI decontamination using activated charcoal (AC) at a dose of 1 to 2 g per kg should be considered for these patients. Multiple doses of AC have no proven benefit and may be harmful in potentially causing obstruction. The risks of forced AC administration usually outweigh any potential benefit when a patient will not voluntarily drink the AC. However, this risk/benefit ratio should be reassessed should a patient clinically deteriorate to the point of requiring intubation. Occasionally, whole bowel irrigation (WBI) is also employed for these patients (see below). Given the lack of end point (i.e., passed packets) in most of these patients, they will require a period of sufficient observation. The safest approach to these patients would be admission for a minimum of 24 hours of close hemodynamic observation, with additional observation time should any unexplained increase in pulse or blood pressure occur. Note this observation period may not be sufficient for all patients; cases of toxicity have resulted from more than 36 hours from ingestion of a sealed baggie [5].

Asymptomatic body packers should also be conservatively managed. One proposed guideline involves the oral administration of a water-soluble contrast solution followed by serial abdominal radiographs (see Chapter 97). Whole bowel irrigation with isotonic polyethylene glycol electrolyte solution has also been advocated for GI decontamination based on case reports. Some clinicians advocate administering polyethylene glycol solution, 1 L per hour, to adults until there is no
longer significant concern for retained packets in the GI tract. This is usually signalled by a clear rectal effluent, no radiographic evidence of drug packets in the GI tract, a negative rectal examination for packets, and an accurate accounting of the number of ingested packets. It does appear that the packet count for body packers is sometimes more reliable than for body stuffers, but still may not be correct. Administration of multiple doses of cathartics is not considered whole bowel irrigation and may result in severe fluid and electrolyte abnormalities [40,41].

Body packers and body stuffers who develop sympathomimetic toxicity should be suspected of having leakage or rupture of the drug packets in their GI tract [42]. In the case of a body packer, this is an absolute indication for emergent surgical intervention owing to the massive amount of drug present and profound subsequent local (e.g., bowel ischemia) and systemic effects. Surgical intervention is also indicated for patients with intestinal obstruction, ischemia, or perforation and may be indicated when packets fail to progress through the GI tract after conservative management. Endoscopic retrieval of packets retained in the stomach is rarely performed owing to risk of rupture, but if attempted, it should be by an experienced endoscopist.

The proper management of patients exposed to methamphetamine laboratories varies depending on the exposure scenario and the type of laboratory. Most of the times, the only treatment required is adequate burn care because many of these patients present with thermal burns from a laboratory fire. The most dangerous components to a methamphetamine laboratory not on fire (besides the occasional armed psychotic inhabitant) are the potential gases: anhydrous ammonia, hydrochloric acid (HCl), and phosphine. Of note, the type of possible gases present depends on the type of lab as well as the activity state of lab because generally the HCl and phosphine levels are present only in high enough levels to cause injury during the process of the “cook” [43,44]. All three gases can cause significant acute lung injury, with the injury from phosphine potentially being delayed by several hours and anhydrous ammonia potentially causing significant ocular and dermal injury as well. Methamphetamine laboratories also use caustics and solvents that on contact with skin or eyes can cause significant injury. Variations in the synthesis methods, exposure duration, and preexisting conditions as well as chapter space make it difficult to give further exacting treatment recommendations. It should be noted that despite the subjective complaints, a minor transient exposure to a methamphetamine laboratory is unlikely to cause significant injury, and that unless gross contamination is present, a gentle cleaning with soap and water is adequate for nearly all exposures [45].

Chapter 101

Antiarrhythmic Agents

STEVEN B. BIRD

The therapeutic use, misuse, and intentional overdose of antiarrhythmic drugs are associated with severe morbidity and mortality [1]. The recognition, management, and prevention of antiarrhythmic toxicity require an understanding of the pharmacology of these drugs as they relate to cardiac electrophysiology. A general review of the mechanisms involved as well as the principles of management of poisoning is followed by a discussion of individual agents.

PHARMACOLOGY

Antiarrhythmic drugs are most commonly classified on the basis of their predominant physiologic effects and mechanism of action as originally proposed by Vaughan Williams [2] and Campbell [3] (Tables 101.1 and 101.2; Fig. 101.1).

| IA    | Quinidine  
        | Procainamide  
        | Disopyramide  
        | Moricizine  | Reduce rate of depolarization; prolong duration of action potential | Moderate slowing of cardiac conduction; prolongation of refractory periods |
| IB    | Lidocaine  
        | Mexiletine  
        | Tocainide  | Reduce rate of depolarization selectively in ischemic cells; shorten action potential duration | Selective depression of ischemic tissue; may shorten refractory periods |
| IC    | Flecaïnide  
        | Propafenone  | Marked depression of depolarization rate | Marked slowing of cardiac conduction; small increase in refractory periods |
Typical cellular action potentials recorded from working myocardium (upper trace) and the atrioventricular node (lower trace). The nodal cell has an action potential of smaller amplitude, with a much slower rate of depolarization in phase 0. The nodal cell exhibits spontaneous diastolic (phase 4) depolarization ("pacemaker" activity). Rapid depolarization in phase 0 (atrial and ventricular cells and Purkinje fibers) is produced by a fast inward sodium current (depressed by class I drugs). A slower inward calcium current is also present but is the only inward current found in sinoatrial and atrioventricular nodal cells. This explains their slower rate of depolarization in phase 0 and their sensitivity to calcium channel blockers. Repolarization (phase 3) is produced by a number of outward potassium currents; the rapid component of the delayed rectifier potassium current is the most important. Blockade of this current by antiarrhythmic or other drugs prolongs repolarization and action potential duration (class III action).

The major effect of class I agents is blockade of the fast inward sodium current responsible for the rapid upstroke and conduction of the action potential [4] (see Fig. 101.1). This effect is also known as local anesthetic
or membrane stabilizing action. Class I drugs depress automaticity, particularly in Purkinje fibers. Class I drugs comprise a large group of antiarrhythmic agents, many of which have diverse electrophysiologic properties; consequently, this class has been subdivided into classes IA, IB, and IC (see Table 101.2) [3].

The class II antiarrhythmic drugs are β-adrenergic antagonists; they inhibit the proarrhythmic effects of catecholamines, which shorten refractory periods and facilitate reentrant circuits. The slowly conducting, calcium channel–dependent action potentials of the normal sinoatrial (SA) and atrioventricular (AV) nodes (see Fig. 101.1) rely partially on sympathetic tone. Class II drugs depress conduction and automaticity through these specialized tissues, leading to bradycardia and AV block. Toxicity due to β-blockers is covered further in Chapter 106.

Class III agents prolong the refractory period by increasing the cardiac action potential duration (APD), especially in phases 2 and 3 (see Fig. 101.1). This effect is produced by blockade of the major outward potassium-rectifying (repolarizing) current, of which amiodarone is the prototypic class III agent.

Class IV drugs (calcium antagonists or calcium channel blockers) antagonize the slow inward calcium current responsible for the slow upstroke and conduction of the action potentials of SA and AV nodal cells [4] (see Fig. 101.1). Verapamil, diltiazem, and nifedipine represent the three subclasses of calcium channel antagonists. Both verapamil and diltiazem have negative inotropic and chronotropic properties and are useful for slowing the ventricular response rate for patients with atrial fibrillation. During therapeutic dosing, calcium channel antagonists such as nifedipine have little effect on cardiac conduction or inotropic state and are, therefore, not used for their antiarrhythmic properties. Calcium channel blocker toxicity is discussed in Chapter 107.

Adenosine and digoxin are two drugs with antiarrhythmic effects that do not fall within the Vaughan Williams classification. Adenosine is an endogenous nucleoside that produces AV nodal conduction block and vasodilation via specific adenosine-sensitive receptors. The antiarrhythmic properties and toxicity of digoxin are discussed in Chapter 108.

The cellular electropharmacology of antiarrhythmic agents involves suppression of automaticity, decreased cardiac conduction, and refractory period prolongation. Automaticity, the spontaneous depolarization of pacemaker myocytes, occurs in the SA and AV nodes as well as in Purkinje fibers. In SA and AV nodal cells, the rate of firing depends on several different inward and outward currents; the combination of currents renders these cells relatively insensitive to depression by antiarrhythmic drugs [1,4]. In Purkinje fibers, however, automaticity occurs as an escape phenomenon that arises in the presence
of AV block. Escape beats probably result from the action of a single inward sodium channel (the “pacemaker current”) and are suppressed by therapeutic concentrations of most class I antiarrhythmic agents. Therefore, Purkinje fiber automaticity is more susceptible to depression by antiarrhythmic agents than is sinus node automaticity. Nonetheless, clinical suppression of the sinus node leading to asystole, particularly in the presence of the high vagal tone commonly seen in the early phases of acute myocardial infarction, is an uncommon but well-recognized complication of therapy with antiarrhythmic agents such as lidocaine.

Reentrant circuit arrhythmias depend on conduction rates around the circuit and the refractory periods of pathway components. If the conduction time falls below the refractory period of part of the circuit, the “excitable gap” disappears, the advancing wavefront meets only refractory tissue, and the arrhythmia terminates. An ideal antiarrhythmic agent would, therefore, accelerate conduction and prolong refractoriness within the substrate for reentry. Many antiarrhythmic agents prolong refractory periods in myocardium, but none accelerates conduction at therapeutic concentrations. Almost invariably, conduction tends to slow. This combination of decreasing conduction and refractory period prolongation can be either proarrhythmic or antiarrhythmic. However, clinicians cannot predict which outcome will occur for a given drug in a given patient. Some antiarrhythmic agents (in particular, class IB drugs and amiodarone [3]) show selectivity for depressing conduction of ischemic or otherwise abnormal myocardium by binding preferentially to the inactivated state of the sodium channel. A complete conduction block through an ischemic segment of a reentrant circuit may be the mechanism of arrhythmia termination; this could occur without slowing conduction in healthy myocardium. Other drugs tend to show less selectivity and depress conduction in normal myocardium at therapeutic concentrations, probably explaining the greater propensity of class IC drugs to be proarrhythmic during both therapeutic use and overdose [3].

Although most antiarrhythmic agents prolong refractoriness, lidocaine, mexiletine, and tocainide tend to shorten it, particularly at low concentrations; this may explain some cases of drug-associated arrhythmogenesis of patients with reentrant tachycardias. Lengthening of refractoriness should be proarrhythmic, but if conduction is slowed simultaneously, the net effect on the reentrant circuit determines the outcome.

Antiarrhythmic drugs suppress most forms of automaticity known to cause tachyarrhythmias. The major exception to this rule is the form of
triggered automaticity due to *early after-depolarizations* (EADs). EADs can be defined as a marked slowing of repolarization, visible on the action potential recording and due to reduction of the normal repolarizing outward potassium current. If voltage conditions are appropriate, prolonged depolarization may trigger a series of automatic action potentials. The upstrokes of these action potentials are due to inward current flow through the normal calcium channels that had been inactivated, had recovered from inactivation, and had found the membrane potential still within their activation range. The channels then reactivate and produce a secondary upstroke. Increased intracellular calcium concentrations activate calcium-sensitive potassium channels and accelerate repolarization. This process can occur as a single event or as an oscillatory series of action potentials, depending on the prevailing conditions of voltage and calcium levels [5].

The induction of EADs may be the basis of arrhythmias, including torsade de pointes associated with long QT syndromes [6]. According to this theory, the slowing of repolarization leads directly to the QT wave prolongation, often with associated prominent, bizarre TU waves. Any triggered activity, should it occur, results in ventricular tachyarrhythmias.

The class IA antiarrhythmic agents quinidine, disopyramide, and procainamide are all capable of producing EADs and torsade de pointes. This is also true of the class III drugs, such as amiodarone, sotalol, ibutilide, and dofetilide. The class IB agents, lidocaine, mexiletine, and tocainide, do not produce EADs and do not cause torsade de pointes. Class IC compounds infrequently cause significant slowing of repolarization and have not been shown to cause torsade de pointes. Of the class IV agents, only mibefradil has an effect on repolarization, which usually manifests as TU-wave changes. Experimental models suggest that this effect is not proarrhythmic; however, there has been a report of torsade due to QT prolongation from therapeutic dosing of mibefradil [7].
CLINICAL PRESENTATION

Toxicity common to therapeutic doses and overdoses of antiarrhythmic agents include depression of automaticity and cardiac conduction, which may be caused by a combination of direct electrophysiologic and secondary metabolic effects. Symptoms following acute overdose usually begin within 4 hours and can occur at any time during chronic therapy. Drug absorption may continue for many hours following the ingestion of large doses, sustained-release preparations, or agents with anticholinergic effects, resulting in delayed or progressive toxicity. Respiratory depression and hypotension produce acidosis and myocardial ischemia that further aggravate depressed conduction. Cardiac manifestations include QRS prolongation, QTc prolongation, sinus node dysfunction, bradycardia, AV block, ventricular arrhythmias, and poor ventricular function. These derangements can culminate in intractable arrhythmias, cardiogenic shock, or death. Manifestations of acute toxicity may also include dizziness, visual disturbances, psychosis, anticholinergic symptoms, hypoglycemia, hyperglycemia, and hypokalemia. Seizures may result from class I (particularly IB) toxicity. Procainamide and quinidine can cause hypotension if infused too rapidly.

Warning signs that indicate an increased risk of torsade include a QTc interval greater than 560 ms, previous history of torsade, bradycardia, increased frequency and complexity of ventricular premature beats, or a ventricular premature beat falling on the T wave [8].

The electrocardiogram (ECG) may provide a clue to the agent or class involved for cases where the drug ingested is not known. Class IB drugs usually have no effects on the QT interval; whereas class IA, IC, and III agents prolong it. With class IA agents, QT prolongation is due to slowing of both depolarization and repolarization. Hence, both the QRS duration and JT interval are increased. In contrast, QT prolongation primarily results from slowed depolarization with class IC agents, resulting in an increased QRS (but not JT) duration and from prolonged repolarization with class III agents, resulting in an increased JT (but not QRS) interval.

The differential diagnosis of bradyarrhythmias includes β-blocker, calcium channel blocker, cholinergic agent (carbamate and organophosphate insecticides), clonidine, cyclic antidepressant, and digitalis poisoning. Other agents that cause QRS and QT interval prolongation include antihistamines, antipsychotic agents, cyclic
antidepressants, magnesium, and potassium. Ventricular tachyarrhythmias may occur with poisoning from sympathomimetics. Hypoglycemia, hypoxia, and metabolic disturbances should be considered in the differential diagnosis of patients with neurologic symptoms.
DIAGNOSTIC EVALUATION

Physical examination should focus on vital signs and respiratory, cardiovascular, and central nervous system (CNS) function. Frequent vital signs and continuous cardiac monitoring should be performed. Essential tests include an ECG and serum electrolytes, blood urea nitrogen, creatinine, and magnesium measurement; liver function tests and serum drug levels, if available, may also be helpful. A chest radiograph should be obtained as clinically indicated. Patients with hypotension and hypoxemia should have arterial blood gas and serum lactate measurements.
MANAGEMENT

The general features of antiarrhythmic drug overdose and their management are discussed below (Table 101.3). Care of the antiarrhythmic poisoned patient centers on general supportive and critical care principles. Unique aspects pertinent to individual drugs are discussed in later sections. All patients suspected of ingesting an overdose of an antiarrhythmic agent should receive oral activated charcoal. Patients with complications of therapeutic dosing may also benefit from oral activated charcoal to reduce absorption of a recently administered drug dose. The greatest amount of absorption to charcoal will occur when it is given within 1 to 2 hours of the ingestion. CNS and respiratory depression commonly require airway support by endotracheal intubation. Seizures are managed by benzodiazepine therapy. Phenytoin should never be used to treat seizures secondary to drug toxicity because of the risk of increased mortality.

Intravenous lipid emulsion for bupivicaine (may consider for other lipophilic agents or in refractory cases). Loading dose of 1.5 mL/kg administered over 1 min, repeated 1–2 times every 3–5 min as needed. If hemodynamic improvement is noted, the loading dose should be followed by a continuous infusion at a rate of 0.25–0.5 mL/kg/min.

Initial therapy for hypotension involves administration of intravenous fluids. Because poisoned patients are infrequently hypovolemic, fluid administration should be monitored closely. In general, if a response in blood pressure is not seen with 2 L of intravenous fluids, pressors such as norepinephrine should be administered. Early consideration should be given to providing a circulatory assist device for patients with cardiogenic shock. Intra-aortic balloon pump counterpulsation has been used successfully to treat patients with severe quinidine or disopyramide toxicity, and partial cardiac bypass has been used to maintain circulation during massive lidocaine or flecainide toxicity [9].

Decreased ventricular conduction, as measured by QRS prolongation during quinidine, procainamide, flecainide, and encainide toxicity, are often treated with sodium bicarbonate infusion [10,11]. In animal studies, hypertonic sodium bicarbonate reverses ventricular arrhythmias caused by flecainide toxicity [12] and reverses hypotension due to tricyclic antidepressants with class IA antiarrhythmic effects. Hypertonic sodium bicarbonate should be considered for the treatment of QRS widening greater than 100 ms or ventricular tachyarrhythmias in the setting of class IA or IC drug toxicity. Common practice is to administer intravenous boluses of sodium bicarbonate (50 mEq of 1 mEq per mL solution) as needed to increase and maintain blood pH between 7.45 and 7.55. As an alternative, a continuous infusion of 1,000 mL of 5% dextrose in water containing 2 to 3 ampoules of sodium bicarbonate and
potassium chloride is an option. Bicarbonate should be administered for 12 to 24 hours and then gradually withdrawn while watching for QRS lengthening to recur. At present, there is no evidence that prophylactic alkalization before QRS widening changes outcome. For the most severely poisoned patients, however, alkalization may be ineffective, especially if there is persistent metabolic acidosis. In a series of patients with class I antiarrhythmic drug overdose requiring cardiopulmonary resuscitation, only 2 of 29 survived despite the use of hypertonic sodium bicarbonate [13].

Sodium bicarbonate appears to act by increasing the extracellular sodium concentration and reducing the drug-induced sodium channel blockade [14]. Hypertonic sodium chloride has proven effective for animals and, anecdotally, in humans, but sodium bicarbonate is generally preferable because increasing pH is equally or more important in some models [14] (see Chapter 97 for more detail).

The treatment of recalcitrant ventricular tachycardia typically consists of repeated cardioversions, cardiopulmonary resuscitation, vasopressor support, and mechanical ventilation. Treatment with other class IA and IC antiarrhythmic drugs is contraindicated, given the potential for further arrhythmia aggravation [15]. Lidocaine may be considered because it does not depress conduction, but it is often ineffective. Suppression of ventricular tachycardia and hemodynamic improvement has been anecdotally described with sodium bicarbonate [10, 11]. Overdrive pacing may also be effective.

The treatment of torsade de pointes should include 1 to 2 g of a 25% solution of intravenous magnesium sulfate. Direct-current cardioversion is often effective in terminating torsade de pointes, but it frequently recurs. Increasing the ventricular rate to greater than 90 to 110 beats per minute by an infusion of isoproterenol or ventricular pacing may also be effective [16]. In one study, infusion of potassium chloride at 0.5 mEq per kg for 60 to 90 minutes normalized excessive quinidine-induced QT prolongation, but simply correcting hypokalemia did not suppress torsade de pointes [17]. Lidocaine is inconsistently effective [18]. Treatment with class IA or III antiarrhythmic drugs is contraindicated because further prolongation of repolarization and the QT interval may exacerbate torsade de pointes. Magnesium therapy should also be considered for patients at increased risk for this arrhythmia (see above); it has been found to prevent occurrence of torsade in a dog model (dose of 30 to 60 mg per kg) [19].

Although most antiarrhythmic drugs are weak bases, urine
acidification is contraindicated because systemic acidosis may aggravate cardiotoxicity; treatment with hypertonic alkaline solution to reduce cardiotoxicity is likely to be of greater benefit. Hemodialysis is of limited benefit for antiarrhythmic toxicity because drug clearance is limited by protein binding and high lipid solubility [20]. Hemoperfusion using charcoal resin is more effective for removing drugs with high protein binding and high lipid solubility; however, this modality is rarely available. Hemoperfusion is of greatest value for disopyramide [21] or N-acetylprocainamide (NAPA) toxicity [22].
INDIVIDUAL AGENTS

Class IA Agents

Quinidine

Quinidine is administered orally as sulfate or gluconate. The usual dose of immediate-release quinidine sulfate is 200 to 400 mg, 4 times per day, with gluconate doses being approximately 30% higher. Bioavailability is approximately 70% for both forms; peak plasma levels are reached earlier for the sulfate (60 to 90 minutes) than for the gluconate. Quinidine is metabolized by CYP3A4 to 3-OH quinidine and quinidine-N-oxide; these metabolites have less electrophysiologic activity than do quinidine [23]. Details of pharmacokinetics are listed in Table 101.4.

<sup>a</sup>Shorter with lower urine pH.

<sup>b</sup>Correlates poorly with therapeutic effect.

<sup>c</sup>Longer in patients with congestive heart failure.

<sup>d</sup>Dose dependent.

<sup>e</sup>Slow metabolizers at CYP2D6 locus.

HD, hemodialysis; HP, hemoperfusion; NAPA, N-acetylprocainamide.

Torsade de pointes is an adverse effect of therapeutic doses of quinidine (also known as quinidine syncope). Risk factors for this arrhythmia are recent initiation of quinidine therapy, concurrent digoxin therapy, female gender, structural heart disease, hypokalemia, and hypomagnesemia. Possible mechanisms include prolongation of the QTc interval and potentiation of EADs [23].

At therapeutic doses, sustained-release quinidine formulations produce therapeutic plasma concentrations for up to 8 hours for most patients. In overdose, however, saturation of enzymes that metabolize the drug may dramatically prolong serum concentrations. Consequently, serial serum drug monitoring is warranted (see Table 101.4), especially when potentially interactive agents, are coadministered. Agents that are CYP3A4 inhibitors, such as cimetidine, can increase quinidine serum concentration. Mild quinidine overdose presents as cinchonism (headache, tinnitus, deafness, diplopia, confusion), vertigo, visual disturbances (blurred vision, photophobia, scotomata, contracted visual fields, yellow vision), or delirium. Severe toxicity is characterized by CNS toxicity (lethargy, coma, respiratory depression, seizures), gastrointestinal tract toxicity (nausea, vomiting, diarrhea), and cardiovascular collapse [24]. Noncardiac side effects include nausea, cinchonism, thrombocytopenia, and drug-induced fever.

Initial therapy for acute quinidine overdose should include gastric decontamination with activated charcoal. Treatment of CNS toxicity is supportive, with intubation and ventilation for CNS depression and benzodiazepines for seizures. Deaths from quinidine overdose are usually secondary to arrhythmias or hypotension. When pacing is indicated for bradycardia, failure to capture is common in the face of drug-induced
myocardial depression. QRS prolongation should be treated with bicarbonate infusion. Hypotension may result from vasodilation from β-adrenergic blockade, impaired contractility from sodium channel blockade, or arrhythmias. Vasodilation may be treated with fluid administration and β-acting vasopressors such as norepinephrine; large doses may be required. Refractory hypotension has been successfully treated with an intra-aortic balloon pump and partial circulatory bypass.

**Procainamide**

Procainamide is eliminated by hepatic metabolism and renal excretion [25]. The major metabolite is NAPA, which has potent class III and some class I antiarrhythmic activity [26]. In fast acetylators or in renal failure, as much as 40% of a dose of procainamide may be excreted as NAPA. Because the prevalence of the fast and slow acetylator phenotypes varies between ethnic groups, widely variable procainamide and NAPA concentrations may occur in specific populations. Blood concentrations of NAPA may exceed those of the parent drug, given its dependence on renal elimination.

The cardiovascular side effects of procainamide are very similar to those of quinidine except that the drug has no α-adrenergic antagonist activity. Acute procainamide toxicity is manifested primarily by hypotension, but QRS widening and ventricular arrhythmias may also occur [27]. Inappropriate drug dosing in renal insufficiency or before achieving steady-state concentrations is the most common cause of procainamide toxicity. Toxic levels of NAPA (>25 µg per mL) may begin to accumulate as a result of acute or chronic renal insufficiency, potentially leading to torsade. Approximately 40% of patients receiving long-term oral therapy with procainamide develop a syndrome resembling systemic lupus erythematosus that usually resolves after drug withdrawal [28].

Signs and symptoms of acute procainamide overdose are similar to those of quinidine overdose. Patients with non–life-threatening procainamide toxicity (e.g., hypotension) and adequate renal function can be managed with supportive care. Seizure has been reported after a pediatric ingestion. Hypertonic sodium bicarbonate may be useful for QRS prolongation, monomorphic ventricular tachycardia, or hypotension. This therapy has minimal benefit in NAPA toxicity because this metabolite has primarily class III effects. Torsade de pointes should be treated as discussed above. Anecdotal reports have showed increased
procainamide and NAPA clearance with hemodialysis or hemoperfusion; however, clinical significance is unclear [22,27].

**Disopyramide**

Disopyramide, unlike most other antiarrhythmic drugs, has protein binding that shows nonlinear, saturable characteristics [29]. This is clinically important because small increases in total plasma level within the therapeutic range (see Table 101.3) may mask larger rises in free (active) drug concentration. When administered intravenously, disopyramide produces hypotension less frequently than does quinidine or procainamide. Widening of the QRS complex, prolongation of the QT interval, and drug-induced ventricular tachyarrhythmias have all been reported as side effects [30]. There are numerous reports of either QTc prolongation, torsade, or monomorphic ventricular tachycardia from the interaction of disopyramide and macrolide antibiotics. Erythromycin, clarithromycin, and azithromycin have all been implicated; a possible mechanism is inhibition of hepatic CYP3A4.

Acute disopyramide overdose is similar to that of quinidine or procainamide, with QRS prolongation, severe refractory hypotension, and arrhythmias [31,32]. Hypoglycemia is a recognized adverse effect. Data regarding management are limited, but an approach similar to that for quinidine toxicity is appropriate. Hypotension refractory to intravenous fluids and vasopressors has been treated with an intra-aortic balloon pump. Because of its relatively small volume of distribution, disopyramide clearance is substantially increased by hemoperfusion [21].

**Class IB Agents**

**Lidocaine (and Other Local Anesthetics)**

Amide-type local anesthetics (e.g., articaine, bupivacaine, etidocaine, lidocaine, mepivacaine, prilocaine, ropivacaine) are extensively metabolized by hepatic dealkylation, hydrolysis, ring hydroxylation, and conjugation. Ester-type agents are metabolized by hepatic and plasma esterases. Derivatives of para-aminobenzoic acid (e.g., benzocaine, procaine, tetracaine) are predominantly hydrolyzed by plasma pseudocholinesterase, whereas other esters (e.g., cocaine, dyclonine, proparacaine) are predominantly metabolized in the liver [33]. Allergic cross-reactivity occurs within the amide and ester groups but not between them.
Extensive first-pass metabolism prevents effective oral therapy with lidocaine and local anesthetics, but toxicity can occur after ingestion [33]. The maintenance infusion rate of lidocaine must be reduced for patients with cardiac failure or hepatic dysfunction and among the elderly. Plasma concentrations should be monitored for infusions lasting longer than 24 hours. Lidocaine has two active metabolites, monoethylglycine xylidide (MEGX) and glycine xylidide (GX). Although these metabolites have short elimination half-lives of 2 hours and 1 hour, respectively, they may contribute significantly to toxicity, which can occur several hours after an infusion is started [33]. Most lidocaine toxicity is caused by errors of dosing and administration [34]. Life-threatening toxicity and death have occurred after inadvertent overdose, surgical procedures such as liposuction, and parenteral, mucosal, and topical anesthesia [35]. The safety of tumescent liposuction, in which large volumes of lidocaine solutions are infused subcutaneously, has been called into question following several reported deaths [36].

All local anesthetics have toxicity similar to lidocaine, with neurologic signs and symptoms usually preceding cardiac manifestations, except in massive acute overdose [37]. Neurologic symptoms, the most significant of which is seizures, include auditory disturbances, visual disturbances, paresthesias, and ataxia. Lidocaine has a bimodal concentration-dependent effect on seizures; lidocaine suppresses seizures at concentrations between 0.5 to 5 µg per mL but increases the risk at levels above 8 to 9 µg per mL. The relative contribution to epileptogenicity of the parent compound compared with the metabolites MEGX and GX is still unclear [38]. Adverse cardiac effects from lidocaine administration are unusual in the absence of severe underlying conduction-system disease, acute myocardial ischemia, or massive overdose. Persons with third-degree heart block requiring ventricular arrhythmia suppression should have a prophylactic pacemaker inserted before lidocaine administration. However, lidocaine administration to asymptomatic patients with bundle-branch block or intraventricular conduction disease carries a low risk [39].

Acute massive overdose of lidocaine is characterized by seizures, coma, respiratory arrest, and cardiovascular collapse [37,40]. Hypotension is due to myocardial depression [41]. Lidocaine has little or no effect on the QT interval; however, QRS prolongation, AV block, and depressed automaticity with bradycardia or asystole can occur. Data regarding management are anecdotal. Seizures should be managed using intravenous diazepam; phenytoin should be avoided. Bradyarrhythmias may respond to isoproterenol infusion or cardiac pacing. Hypotension and shock respond to fluid administration and vasopressors such as dopamine. If QRS prolongation is present, hypertonic sodium
bicarbonate may be useful. Intra-aortic balloon pump and cardiopulmonary bypass have been used successfully in patients with circulatory collapse.

Amide-type local anesthetics can also induce methemoglobinemia [33,42]. This effect has been described after percutaneous absorption of benzocaine-containing formulations, during use of prilocaine as an epidural anesthetic agent, and due to prilocaine found in eutectic mixture of local anesthetics (EMLA) cream. Amide agents are hydrolyzed to an amino group that exerts an oxidizing stress in susceptible individuals—such as those with G-6-PD deficiency—to produce methemoglobinemia. In some cases, patients may also exhibit red blood cell hemolysis. Methemoglobinemia is treated with methylene blue (see Chapter 125).

Bupivacaine intoxication can lead to PEA cardiac arrest that is not responsive to standard ACLS protocols. This is a dreaded complication of regional anesthesia after inadvertent intravenous injection of bupivacaine. Intravenous lipid emulsion (Intralipid) is rapidly becoming accepted as standard treatment for bupivacaine-induced cardiac arrest. Even though no human trials exist, there is excellent animal evidence and several human case reports [43]. The mechanism is still unclear, but effects are likely from partitioning of bupivacaine away from cardiac receptors and into an intravenous lipid phase. Therefore, intralipid may be an effective therapy for other lipophilic anesthetic agents. The initial loading dose is 1.5 mL per kg (typically 100 mL in an average adult) administered over 1 minute, which can be repeated 1 to 2 times every 3 to 5 minutes. If hemodynamic improvement is noted, the loading dose should be followed by a continuous infusion at a rate of 0.25 to 0.5 mL/kg/min [44].

**Tocainide**

Adverse effects are common during tocainide therapy, with up to 50% of patients requiring dosage adjustments or discontinuation [45]. The most common side effects are nausea, vomiting, and anorexia, and neurologic effects such as dizziness, paresthesias, tremor, ataxia, and confusion. Tremor suggests that the maximum tolerable dose of tocainide has been reached. Serious toxicity resulting from pulmonary fibrosis in up to 0.1% and agranulocytosis and leukopenia in 0.2% of patients has been reported [46]. Monitoring for clinical or laboratory signs of agranulocytosis has been recommended, particularly during the first 12 weeks of therapy.

Massive tocainide overdose causes effects similar to those of lidocaine overdose: loss of consciousness, seizures, high-degree AV block, asystole, and ventricular fibrillation [45,47]. Treatment considerations are also similar. Because 40% of tocainide elimination is renal, urine acidification
theoretically increases tocainide excretion, but is not recommended because of enhanced systemic toxicity.

**Mexiletine**

Mexiletine is structurally similar to lidocaine and undergoes extensive metabolism in the liver to largely inactive compounds [48,49]. Hepatic impairment can significantly prolong the elimination half-life to 25 hours or longer. Patients with chronic liver disease, such as hepatic cirrhosis, undergo a marked reduction in the hepatic metabolism of mexiletine [50].

Mexiletine is generally well tolerated, with little effect on hemodynamics, even in patients with congestive heart failure [51]. Mexiletine shares much of the side-effect profile of lidocaine, including cross-reactivity in allergic individuals. Dizziness, ataxia, and tremor are relatively common. Overdose effects resemble those of lidocaine. Heart block or asystole accompanied by hypotension occur with massive overdose. Seizures have been reported to occur in the absence of cardiovascular abnormalities, and the prolonged duration of seizures compared with lidocaine overdose may be due to mexiletine’s longer elimination half-life of 5.5 to 12 hours. A urine drug immunoassay was reported as positive for amphetamines in the setting of a mexiletine overdose, likely from cross-reactivity due to structural similarity of these compounds [52].

**Class IC Agents**

**Flecainide**

Flecainide is very well absorbed orally, with negligible hepatic first-pass effect. Flecainide displays polymorphic drug metabolism because it is metabolized via CYP2D6 to active metabolites. This phenomenon effectively results in two distinct populations of patients having very different clearance rates. The average half-life is between 8 and 10 hours, with substantial individual variability. Inhibitors of the CYP2D6 pathway, such as INH, quinidine, selective serotonin-uptake inhibitors, and other agents metabolized by this pathway, may decrease or increase the clearance of flecainide when added to or deleted from therapy. Amiodarone can double the serum concentration of flecainide when the two drugs are concomitantly administered; the flecainide dose should be reduced by 50% when these drugs are coadministered. Serum concentrations can be followed but are rarely used. The proposed therapeutic range is 200 to 1,000 ng per mL.
Flecainide is approved for the management of paroxysmal atrial fibrillation or flutter associated with disabling symptoms, but there are many restrictions owing to its adverse effects. Flecainide has a very narrow therapeutic index and can be toxic even at therapeutic concentrations [53]. In the Cardiac Arrhythmia Suppression Trial (CAST) [54], postinfarction patients being treated for ventricular arrhythmias demonstrated an increased mortality relative to patients treated with placebo. Furthermore, flecainide possesses considerable negative inotropic effects that limit its usefulness in the setting of congestive heart failure. Other dose-related side effects occur, including CNS toxicity such as blurred vision, dizziness, headache, nausea, and paresthesias. Flecainide also increases the ventricular pacing threshold.

Flecainide is highly toxic in overdose; in one series, the mortality rate was 10% [13]. Overdose is characterized by QRS prolongation with a normal JT interval, hypotension, coma, or seizures [13]. Serious cardiac effects that can occur include severe bradycardia, high-grade conduction blocks, and ventricular arrhythmias. Cardiac arrest is not uncommon after overdose; survival after full arrest is rare [53]. Data regarding management are mostly anecdotal. In studies of rats, hypertonic sodium bicarbonate, 3 to 6 mEq per kg, reduced flecainide-induced QRS prolongation [55], and for dogs this treatment largely abolished ventricular tachycardia [12]. For overdose patients, both hypertonic sodium bicarbonate and sodium lactate have been reported to be effective [56]. Hypertonic sodium bicarbonate or sodium lactate should be considered for patients with evidence of disturbed ventricular conduction. Cardiopulmonary bypass and extracorporeal membrane oxygenation (ECMO) have been used to support perfusion until spontaneous perfusion has returned [9,57]. In one report, a patient who developed refractory ventricular fibrillation because of a flecainide overdose was successfully resuscitated after a 300-mg amiodarone bolus was given [53].

Propafenone

Propafenone is used for selected patients with atrial fibrillation and for refractory ventricular tachycardia and fibrillation. Like flecainide, propafenone undergoes significant first-pass hepatic metabolism via the CYP2D6 isoenzyme pathway. Bioavailability ranges from 5% to 50%, depending on the patient’s phenotype; agents that inhibit CYP2D6 lower its clearance rate. Administering propafenone with food may significantly increase bioavailability among extensive metabolizers by diminishing
first-pass drug extraction [58].

Propafenone has other drug interactions as well. Propafenone administration may increase digoxin concentrations between 35% and 85% because of impairment of nonrenal digoxin clearance. Quinidine is a specific and potent inhibitor of CYP2D6 and can significantly increase propafenone concentration [59]. Coadministration of propafenone with warfarin may result in a 25% increase in prothrombin time from unknown mechanisms. Similar to flecainide, propafenone has a narrow therapeutic index.

Propafenone overdose is similar to that of flecainide; toxicity includes QRS prolongation, hypotension, bradycardia, coma, and seizures [13,60]. Seizures appear to be more common with propafenone overdose than with flecainide overdose. PR interval prolongation is a characteristic finding of propafenone toxicity [61]. Hypertonic sodium bicarbonate has been beneficial for QRS prolongations and aberrant ventricular conduction [62]. Benzodiazepines should be used for seizures; phenytoin should be avoided [63]. Management of cardiovascular toxicity is similar to that of flecainide overdose. Transvenous cardiac pacing was successful in a case with severe bradycardia due to a high-grade conduction block [61].

Class III Agents

Amiodarone

Amiodarone was first used as a vascular smooth-muscle relaxant. In addition to its class III activity (prolonging the cardiac APD), amiodarone possesses properties common to all Vaughan Williams classifications. These include calcium channel–smooth-muscle relaxant (class IV), noncompetitive antiadrenergic (class II), and some sodium channel–blocking (class I) activity.

Amiodarone is generally considered the most effective antiarrhythmic agent for treatment and prophylaxis of most types of arrhythmia [64]. Its clinical use, however, is complicated by unusual pharmacokinetics (see Table 101.4) and prevalent side effects [65]. After oral administration, amiodarone widely distributes into body tissues where drug concentration generally exceeds that of the plasma. It is highly lipophilic, highly bound to plasma proteins, and has an extremely long (average, 53 days) elimination half-life [66]. Metabolism occurs in the liver and possibly in the gastrointestinal tract. The major metabolite, desethylamiodarone, accumulates in plasma and tissues and has electrophysiologic properties that are similar to the parent compound [67].

Many side effects are dose dependent, but therapeutic drug monitoring
is of little benefit, except to determine compliance. Evidence suggests a limited correlation between drug level and antiarrhythmic effects \[68\], and serious noncardiac toxicity seems to be more likely at levels above 2.5 µg per mL \[69\].

Pulmonary fibrosis is an important and potentially life-threatening side effect of long-term therapy \[70\]. Pulmonary toxicity is somewhat dose dependant; its prevalence ranges from 5% to 15% in patients who take at least 500 mg per day, but is 0.1% to 0.5% when the dose is less than 200 mg per day \[71\]. Common presenting features include dyspnea, nonproductive cough, fever, and general malaise. A diffuse interstitial pattern on the chest film, similar to congestive heart failure, is the most typical radiographic finding. Symptoms usually resolve with withdrawal of amiodarone therapy. Corticosteroids may improve prognosis and prevent relapse \[71\].

Amiodarone generally does not produce congestive heart failure, even in patients with poor ventricular function, because its vasodilator properties may offset negative inotropic effects. Sinus bradycardia is common during therapy, and symptomatic sinus pauses or sinus arrest can occur in 2% to 4% of patients. AV block may occur in patients with underlying conduction-system disease. Torsade de pointes has been reported, but is much less likely than with other class III agents.

Amiodarone is iodinated and interferes with conversion of thyroxine to triiodothyronine, causing significant elevations of thyroxine and slight reductions in triiodothyronine concentrations \[72\]. Most patients are typically euthyroid, with normal thyroid-stimulating hormone levels. Peripheral neuropathy, tremor, and nervousness develop initially in up to 30% of patients, but these symptoms often improve over time. Asymptomatic corneal microdeposits are present among almost all patients on long-term therapy. Dermatologic effects include increased photosensitivity and blue-gray skin discoloration.

Asymptomatic elevation of hepatic transaminases are relatively common with long-term amiodarone therapy; the reported incidence is 24% to 26%. Transaminases can reach up to 3 times the normal level and resolve with or without discontinuation of therapy \[73\]. Acute hepatitis following intravenous loading of amiodarone is much less common but not infrequently described in the literature \[73\]. Transaminitis can be severe and rarely lead to fatality. Postulated mechanisms include a polysorbate 80 additive used in the intravenous preparation, immunologically mediated injury, or a direct hepatotoxic effect \[74\].

Acute amiodarone overdoses generally tend to follow a benign course. There are several reports of ingestions developing self-limited episodes of ventricular tachycardia, QT prolongation, or mild bradycardia \[75\]. No CNS depression or seizures have been reported. Cholestyramine modestly reduces the elimination half-life of amiodarone from 44 to 28 days,
perhaps by interrupting enterohepatic recirculation [76]. There is likely a role for multidose activated charcoal, even up to 12 hours after the ingestion, because amiodarone has delayed an erratic enteral absorption [77].

**Sotalol**

Sotalol is a β-adrenergic antagonist with class III activity. It is used for the prophylaxis and treatment of AV reentrant and ventricular tachycardias. It has excellent oral bioavailability and is mostly renally excreted unchanged. Overdoses manifest the pharmacologic properties of sotalol; β-adrenergic antagonism causes bradycardia, hypotension, low cardiac output, and CNS depression, whereas the class III activity causes QT prolongation, ventricular ectopy, and arrhythmias, especially torsade de pointes. Reported cases of ventricular arrhythmias due to sotalol overdose are typically associated with bradycardia [77]. Management should include treatment of the β-blocker toxicity (see Chapter 106 for discussion) and control of QT prolongation and torsade de pointes with agents such as magnesium or isoproterenol (see earlier discussion). There are reports of lidocaine suppressing torsade from sotalol overdose [77,78].

**Ibutilide and Dofetilide**

Ibutilide and dofetilide, the first “pure” action potential–prolonging agents, are approved for termination of atrial fibrillation and flutter [79]. Both drugs are structurally similar to sotalol but have no β-blockade effect. They prolong APD by a dual mode of action, initially blocking the rapid component of the delayed rectifier potassium current and enhancing the noninactivating component of the inward sodium current that flows during the plateau (phase 2) of the action potential. The net effect is to increase atrial and ventricular refractory period of APD. Although very little information is available about overdose toxicity, development of torsade de pointes is the major concern. With therapeutic doses, the incidence of this arrhythmia ranged from 3.6% to 12.5% in clinical trials. Most episodes were self-limited, but some were sustained and required cardioversion. Nonsustained monomorphic ventricular tachycardia may also be provoked by ibutilide [80].

**Adenosine**

Adenosine is an endogenous purine nucleoside normally present in all cells of the human body. Intravenous adenosine, administered as a rapid infusion, is used for termination of supraventricular arrhythmias. An
increased heart rate as compensation for peripheral vasodilation has been reported among patients with atrial fibrillation and flutter or if an atrial impulse is conducted via an accessory pathway [81]. Adenosine may also induce atrial fibrillation as a result of the decrease of atrial APD. It should be used with caution among patients with asthma because it can provoke bronchospasm. Short periods (longer than 6 seconds) of asystole are commonly seen after termination of supraventricular arrhythmias.

Therapeutic and toxic doses of adenosine induce intense vasodilation, flushing, and a feeling of pressure or pain in the chest that patients often describe as extremely unpleasant. The duration of these effects is extremely short (measured in seconds) with bolus therapy, but can be prolonged among patients receiving continuous infusions during radionuclide studies or those patients taking dipyridamole [82].
ACKNOWLEDGMENT

The contributions of Dr. Michael Ganetsky on a previous edition of this chapter are appreciated and acknowledged.

Chapter 102

Anticholinergic Poisoning*
KEITH K. BURKHART

The classic anticholinergic syndrome manifests an easily recognizable toxidrome, but patients may present with some, not all, of the classic symptoms. Decreased secretions, tachycardia, mydriasis, and delirium are those most commonly seen. The presence of coingestants and the multiple pharmacologic actions of many anticholinergic drugs may mask anticholinergic manifestations, although anticholinergic effects often persist longer than other pharmacologic actions [1]. The anticholinergic syndrome is more accurately an antimuscarinic syndrome. However, it is conventionally called anticholinergic, and will be referred to as such herein.

Anticholinergic poisoning may result in seizures, delirium, and coma, along with their associated complications. Anticholinergic-induced coma and respiratory failure may require mechanical ventilation. As with any toxicologic emergency, supportive care is of paramount importance. Physostigmine is an effective antidote with proven benefits, but also has a risk for serious adverse events.

EPIDEMIOLOGY AND SOURCES

A variety of pharmaceuticals and naturally occurring products can produce an anticholinergic syndrome (Table 102.1). Many drugs have off-target anticholinergic effects (e.g., histamine-1 [H₁]–blockers, gastrointestinal and genitourinary tract antispasmodics, cough and cold preparations, over-the-counter sleep aids, some opioids, and anticholinergic plants).

Many of these agents have other significant toxic manifestations in addition to their anticholinergic effects.
Pharmaceuticals and plants with anticholinergic action may be intentionally abused for mind-altering effects; especially common is the use of *Datura stramonium* (jimsonweed). Anticholinergic toxicity has occurred by a number of routes other than ingestion, including inhalation of nebulized medication, inhalation of pyrolysis products (e.g., the smoking of plant parts), transdermal use, and ocular instillation.

*The views expressed in this chapter do not necessarily represent the views of the Food and Drug Administration or the United States.*
Anticholinergic agents antagonize the effects of the endogenous neurotransmitter acetylcholine (ACh). Receptors for ACh are widely distributed in the body, including the central nervous system and the sympathetic and parasympathetic ganglia, postganglionic parasympathetic terminals, and motor end plates of the peripheral nervous system.

ACh receptors are divided into two types, muscarinic and nicotinic, based on their ability to bind muscarine or nicotine. This division has a functional significance as well, best described in the peripheral nervous system, where muscarinic receptors predominate in the parasympathetic terminals and nicotinic receptors in autonomic ganglia and motor end plates. Most drugs have predominant effects on one of the two main ACh receptors, but at high doses, there may be some crossover effect. For example, nicotine primarily stimulates nicotinic receptors. Stimulation produces tachycardia, hypertension, muscle fasciculations, and receptor fatigue, with consequent paralysis at high doses. Nicotinic antagonists, such as the nondepolarizing muscle relaxants (e.g., pancuronium), block the action of ACh at the motor end plate and produce skeletal muscle paralysis. Excessive muscarinic receptor stimulation (e.g., organophosphate poisoning) leads to the cholinergic toxirome (see Chapter 109). Agents that block muscarinic receptors may cause anticholinergic toxicity, the focus of this chapter.

Many drugs with anticholinergic properties undergo extensive hepatic metabolism into active and inactive metabolites. A number of these drugs may have half-lives greater than 12 to 24 hours (e.g., tricyclic antidepressants). More important may be the persistence of muscarinic receptor binding. In the intensive care unit (ICU), many patients emerge from coma into a delirious state. Reversal by physostigmine suggests persistent anticholinergic delirium rather than ICU psychosis [1].
Anticholinergic effects have been classically described by the mnemonic “Blind as a bat, Hot as Hades, Dry as a bone, Red as a beet, and Mad as a hatter” in reference to the consequences of ciliary muscle paralysis, hyperthermia, anhidrosis, vasodilation, and delirium, respectively. The toxidrome has been subdivided into the peripheral anticholinergic syndrome and the central anticholinergic syndrome (Table 102.2). The former is caused by quaternary amines (e.g., glycopyrrolate), which are charged molecules that poorly penetrate the blood–brain barrier, whereas the latter is caused by tertiary amines (e.g., atropine), which are uncharged and reach the central nervous system. The most serious anticholinergic manifestations include agitated delirium, hyperthermia, and seizures. Patients may present with primarily peripheral signs and symptoms, primarily central ones, or both. In addition, central symptoms may persist longer than the peripheral manifestations.

The clinical presentation may be complicated by other pharmacologic
actions of the intoxicant (e.g., tricyclic antidepressants and reuptake inhibition of norepinephrine and serotonin or sodium/potassium channel blockade) or the actions of other potentially toxic substances (e.g., salicylates, sympathomimetics).
MANAGEMENT

Traditionally, anticholinergic-poisoned patients have been managed with conservative supportive care. Obtaining and assessing historical and physical data confirms or provides the diagnoses that guide management decisions. Historical data may be simple in terms of a single agent, such as jimsonweed, or complex, as in a polydrug overdose. An analysis of the pharmacologic properties of the known intoxicants guides management decisions.

Delirium and coma are typically the most serious anticholinergic consequences that would require ICU admission. Shortly after exposure, most patients demonstrate sinus tachycardia and hypertension. These abnormalities are usually mild, but occasionally require medical intervention. Patients’ respiratory status should be continuously monitored because of potential for respiratory failure. Hyperthermia, although not often present, is occasionally severe and may require rapid cooling measures. Hyperthermia has also resolved after physostigmine administration. Foley catheter insertion may be needed for urinary retention.

Laboratory studies that should be considered for patients with moderate to severe anticholinergic toxicity include serum electrolytes; blood urea nitrogen; creatinine; and creatine phosphokinase, urinalysis, and electrocardiogram. Rhabdomyolysis and dehydration may be diagnosed. A urine toxicology screen does not detect most anticholinergic agents and typically contributes little to the diagnostic workup or patient management. Many anticholinergic agents are not detected even on comprehensive toxicology screens that take hours to return. Resolution of mental status changes after physostigmine administration may be the most rapid and cost-effective way to arrive at the diagnosis and simultaneously treat the poisoning.

Gastrointestinal decontamination (see Chapters 97 and 125) should be considered, especially for plant ingestions where symptoms persist for days. Administration of activated charcoal is recommended. Its administration, however, may be problematic for the agitated or delirious patient. Physostigmine administration has also been recommended to facilitate activated charcoal administration [2].

Hallucinations, agitation, and delirium have been traditionally treated with benzodiazepines (e.g., diazepam, lorazepam) and butyrophenones.
(e.g., haloperidol). Heavily sedating doses may often be required such that endotracheal intubation becomes necessary [1]. Furthermore, haloperidol use often worsens the anticholinergic delirium and should not be used. Physostigmine, as an antidote, reversibly binds to acetylcholinesterase and prevents this enzyme from degrading ACh, thereby allowing the neurotransmitter to persist, accumulate, and competitively reverse muscarinic receptor inhibition at its postsynaptic sites of action. Physostigmine, as opposed to similar drugs such as neostigmine and pyridostigmine, is a tertiary rather than a quaternary amine and effectively crosses the blood–brain barrier. As a result, it is effective in reversing central as well as peripheral anticholinergic effects. A more liberal use of physostigmine has the potential to help many patients and save resources. Use as a diagnostic tool may avoid an expensive workup. It may also avoid alternative treatment with other drugs and the costs of potentially having to intubate the heavily sedated patient [1].

Physostigmine administration allegedly has contributed to poor outcomes, asystole, seizures, and death, mostly reported after cyclic antidepressant poisoning. When administered in excessive amounts or to a patient not in an anticholinergic state, signs and symptoms of cholinergic excess may appear. A retrospective series of 39 patients treated with physostigmine included cyclic antidepressant poisoned patients [3]. None of these patients developed dysrhythmias or needed atropine, while one patient had a self-limited seizure. Reports have also described the benefits of physostigmine administration following atypical neuroleptics, including clozapine, olanzapine, and quetiapine poisoning [3,4]. Close observation is mandatory following reversal of anticholinergic-induced respiratory or CNS depression, especially early in the course of intoxication. The awakening and cholinergic effects theoretically could enhance gut activity and further absorption of ingested drugs such that when physostigmine is cleared, the patient might have greater toxicity than at the time of first administration.

Physostigmine can be both diagnostic and therapeutic. Administration to the confused, febrile patient may return mental status to normal and reduce fever. A head computerized axial tomogram and lumbar puncture may be avoided if the patient awakens and provides a history that is consistent with the anticholinergic toxicity. On theoretical grounds, it has been suggested that physostigmine may be useful for seizures unresponsive to conventional treatment; severe hypertension resulting in acute symptoms or end-organ dysfunction; and supraventricular tachycardia resulting in hemodynamic instability, cardiac ischemia, or other organ dysfunction. In clinical practice, these indications rarely arise and physostigmine is almost exclusively used as a diagnostic aid and for the treatment of central nervous system excitation (psychomotor
agitation) and coma. In a case series of patients treated by medical toxicologists, physostigmine use was associated with lower rates of intubation [5].

Contraindications to the use of physostigmine include bronchospasm and mechanical obstruction of the intestine or urogenital tract. It should be used with caution among patients with asthma, gangrene, diabetes, cardiovascular disease, or any vagotonic state, and with choline esters or depolarizing neuromuscular-blocking agents (e.g., succinylcholine). Physostigmine should also be used cautiously after cyclic antidepressant overdose and is contraindicated for patients with evidence of cardiac conduction delay (e.g., atrioventricular block and prolonged QRS interval) on electrocardiogram.

Patients receiving physostigmine should be placed on continuous cardiac monitoring and be under continuous careful observation (see Table 102.3). Recommendations for the safe use of physostigmine center on its slow intravenous infusion at a rate not to exceed 0.5 mg per minute to avoid adverse drug events such as bradydysrhythmia and seizures. Slower rates of administration may further reduce the risk for adverse events [6]. The average dose needed for adults is 1 to 2 mg [1,6]. Mental status improvement is usually seen within 5 to 20 minutes of administration. If no reversal of anticholinergic effect has occurred after 10 to 20 minutes, an additional 1 to 2 mg may be administered. Administration by continuous infusion has been used [4]. The recommended dose for pediatric patients is 0.01 to 0.02 mg per kg not to exceed 0.5 mg per minute [5]. The half-life of physostigmine is short, and its duration of action after the 2-mg dose typically is only 1 to 6 hours. The action of many anticholinergic agents persists longer and, therefore, additional doses may be needed [7]. If cholinergic toxicity emerges, atropine is not needed unless severe toxicity develops. Seizures are rare and usually self-limited [3]; an intravenous benzodiazepine is recommended (see Chapter 109). Anecdotally, some physicians have administered lorazepam, 1 mg, before physostigmine as an additional safety measure [8].

### TABLE 102.3 Summary Treatment Recommendations for Anticholinergic Toxicity and Use of Physostigmine

| Place patient on cardiac and pulmonary monitor |
| Obtain electrocardiogram—if QRS prolonged more than 100–110 ms, physostigmine |
should not be used
Consider a urinary catheter
Consider pretreatment with 1 mg lorazepam IV before physostigmine
If no QRS prolongation, administer 2 mg physostigmine IV over 4 min
If no resolution of delirium and no bradycardia or seizures, consider repeat dosing of 1–2 mg physostigmine IV
If appropriate response, repeat 1–2 mg physostigmine as necessary, continuous infusion may be useful in rare circumstances
REFERENCES

Anticonvulsants can be divided into four groups based on their primary mechanism of action: those that primarily act on neuronal membranes (membrane-active agents), those that act on neurotransmitters or their receptor sites (synaptic agents), those with multiple sites of action, and those that are not yet understood. Membrane-active agents alter ion fluxes and include carbamazepine (CBZ), oxcarbazepine, ethosuximide, zonisamide, phenytoin, and lamotrigine (LTG). Synaptic agents primarily affect the activity of gamma-aminobutyric acid (GABA) and include barbiturates, benzodiazepines, gabapentin (GBP), tiagabine, and vigabatrin. Agents that have multiple sites of action include valproate, GBP, felbamate, and topiramate, and those for which mechanisms of action still are not understood are levetiracetam, stiripentol, and remacemide [1,2]. (Barbiturates and benzodiazepines are discussed in Chapter 123.) The precise action mechanisms of many of the newer anticonvulsants also remain unknown. Even within groups, the site or mechanism of action may differ. Pharmacologic differences are important from a therapeutic standpoint. For the treatment of seizures, combining agents from different groups may be effective whenever a single agent is ineffective or requires a toxic dose for efficacy. Therapeutic synergism may also occur when different agents of the same group are combined (e.g., benzodiazepines and barbiturates).

PHENYTOIN

Phenytoin (diphenylhydantoin) is the most commonly used anticonvulsant medication. It is also used in the treatment of trigeminal neuralgia. Iatrogenic intoxications can occur with drug interactions because distribution, protein binding, and clearance of phenytoin are affected by other medications and disease states. Toxicity may occur when the daily administered dose exceeds endogenous metabolism and
elimination [3]. Toxicity may also result when switching dosage forms or between generic and proprietary forms of the drug because of different release and absorption characteristics. Idiosyncratic and hypersensitivity reactions associated with therapeutic use are unrelated to dose, and are most commonly seen among patients with underlying neurologic disorders [4].

**Pharmacology**

Phenytoin is the prototypical membrane-active anticonvulsant. It acts on sodium pumps and channels in excitable cell membranes and is classified as a type 1B antidysrhythmic agent. By blocking the accumulation of intracellular sodium during tetanic stimulation, it limits the posttetanic potentiation of synaptic transmission and prevents seizure foci from detonating adjacent areas.

Phenytoin is a weak acid, with a $pK_a$ of 8.5. The intravenous (IV) form has a pH of 10 to 12, contains 50 mg per mL, and is dissolved in a 40% propylene glycol and 10% ethanol vehicle. The phenytoin prodrug fosphenytoin (Cerebyx) has a pH between 8.6 and 9.0 and greater solubility. It is compatible with common IV preparations, lacks the cardiotoxic diluent propylene glycol, and may be administered intramuscularly as well as intravenously. It has a conversion half-life of 8.4 to 32.7 minutes to active phenytoin and is dosed in phenytoin equivalent (PE) units (75 mg per mL of fosphenytoin equals 50 mg per mL of phenytoin) [5]. In many institutions, fosphenytoin has replaced phenytoin.

Absorption occurs in the duodenum but depends on dosage form, gastric emptying, and bowel motility. Peak levels occur between 2.6 and 8.9 hours after oral dosing of an extended-release capsule. During overdosage, absorption may continue for up to 7 days, possibly due to decreased gastric motility and pharmacobezoar formation. The volume of distribution ($V_d$) of phenytoin is 0.6 L per kg, and it distributes preferentially into the brainstem and cerebellum, which explains the effects seen in overdose. Phenytoin is highly protein bound; decreased protein binding increases the free, pharmacologically active form of the drug and the $V_d$. Because usually only total phenytoin levels are measured, toxicity from increased free phenytoin may occur at lower total phenytoin levels [3].

Hepatic metabolism of phenytoin follows first-order elimination kinetics, with an average half-life of 22 hours (range: 7 to 55 hours). When plasma levels exceed $10 \, \mu g$ per mL, metabolism follows zero-order elimination kinetics, yielding a much longer half-life. The enzyme system may be induced or inhibited by other drugs, inherited genetic disturbances, or liver disease [6,7].
The anticonvulsant effects of phenytoin occur with plasma levels between 10 and 20 μg per mL. This can be achieved within 45 to 60 minutes by an IV-loading dose of 15 to 20 mg per kg of phenytoin or PE units of fosphenytoin. The rate of IV phenytoin administration should not exceed 50 mg per minute because of propylene glycol toxicity [8]. To avoid hypotension, fosphenytoin administration should not exceed 150 PE units per minute. Phenytoin has been successfully administered by the interosseous route in children with poor venous access. Maintenance dosing is usually 4 to 6 mg/kg/d in single or divided doses, although neonates may require higher doses (5 to 8 mg/kg/d) [9]. Death from isolated phenytoin ingestions is unusual but has been reported in young children with ingestions of 100 to 220 mg per kg. Death results from central nervous system (CNS) depression with respiratory insufficiency and hypoxia-related complications.

Clinical Manifestations

Toxicity resulting from acute and chronic intoxication has a similar presentation. Patients with serum phenytoin concentrations between 20 and 40 μg per mL typically have nausea, vomiting, normal to dilated pupils, nystagmus in all directions, blurred vision, diplopia, slurred speech, dizziness, ataxia, tremor, and lethargy [10]. They may also be excited and agitated. As phenytoin serum concentration increases, confusion, hallucinations, and apparent psychosis may develop. Progressive CNS depression occurs, and nystagmus may improve. Pupillary response becomes sluggish, and deep tendon reflexes diminish. Severe toxicity with coma and respiratory depression occurs with serum concentration exceeding 90 μg per mL [11]. Slowing of alpha wave activity is seen on electroencephalograms. As toxicity increases, brainstem-evoked potentials are suppressed and may be absent. Paradoxical hyperactivity has been reported among patients with underlying neurologic deficits, with findings of dystonia, dyskinesia, choreoathetoid movements, decerebrate rigidity, and increased seizure activity [12]. Patients with baseline focal neurologic deficits may show contralateral abnormalities, including hemianopia, hemianesthesias, and hemiparesis. Patients recover completely if no anoxic or hypoxic complications develop during acute toxicity. Cerebellar atrophy after acute intoxication with phenytoin that was not known to be attributed to hypoxia has been reported, however. Recovery may take 1 week or longer.

In rare instances, chronic toxicity has been associated with a syndrome
of inappropriate antidiuretic hormone, encephalopathy, and cerebellar degeneration [13]. Chronic use of phenytoin causes hyperglycemia, vitamin D deficiency and osteomalacia, folate depletion, megaloblastic anemia, and peripheral neuropathy. Other adverse drug events include altered collagen metabolism that causes hirsutism, gingival hyperplasia, keratoconus, and hypertrichosis [14].

Non-dose-dependent phenytoin adverse drug events include hypersensitivity reactions such as fever, rash, eosinophilia, hepatitis, lymphadenopathy, myositis, a lupus-like syndrome, rhabdomyolysis, nephritis, vasculitis, and hemolytic anemia [4]. Phenytoin administration during pregnancy has resulted in fetal hydantoin syndrome.

Phenytoin-induced dysrhythmias, hypotension, congestive failure, respiratory arrest, and asystole result predominately from propylene glycol toxicity during rapid IV phenytoin administration (e.g., >50 mg per minute). If the rate of infusion is slowed or temporarily halted, these effects usually resolve spontaneously but may persist for 1 to 2 hours [15]. Cardiovascular toxicity from phenytoin intoxication itself is rare, represents significant toxicity, and primarily occurs in patients with underlying cardiac disorders [16].

Diagnostic Evaluation

Essential laboratory studies should include sequential serum phenytoin levels (free and total, if available) and levels of other anticonvulsant medications, particularly when enteric-coated dosage form is involved. The interval between drug levels should be based on factors such as severity of intoxication, rate of rise of levels, and time since exposure. Intervals should be more frequent during the initial evaluation phase, while absorption is still occurring, than later, during the postabsorptive phase. In stable patients whose drug levels have peaked or started to decline, it may be appropriate to obtain levels every 12 to 24 hours until they return to the therapeutic range. Recommended laboratory studies include serum complete blood cell count, electrolytes, blood urea nitrogen, creatinine, glucose, albumin, and liver function tests. In hypoalbuminemic patients, the corrected phenytoin concentration is equal to the measured phenytoin concentration multiplied by 4.4 and divided by the serum albumin level. In all deliberate overdoses, an electrocardiogram (ECG) and acetaminophen and salicylate levels should be obtained. Arterial blood gas, chest radiograph, head computed tomography, and lumbar puncture should be obtained as clinically indicated.

The differential diagnosis of phenytoin intoxication includes sedative–hypnotic agents, other anticonvulsants, phencyclidine, neuroleptic agents, and other CNS depressant drugs. Other conditions such as
diabetic ketoacidosis; hyperosmolar nonketotic coma; sepsis; CNS infection, tumor, and trauma; seizure disorders; extrapyramidal syndromes; postictal states; and cerebellar abnormalities may also mimic phenytoin intoxication.

**Management**

Patients should have a rapid evaluation of respiratory status followed by intubation if hypoxia or risk of aspiration is present. Vascular access should be established and the patient placed on continuous cardiac monitoring. If the mental status is abnormal, a fingerstick blood sugar should be obtained. Patients who are hyperglycemic from phenytoin intoxication can be treated with discontinuation of the drug; insulin therapy is rarely required. Flumazenil, the benzodiazepine antagonist, has no role in managing phenytoin intoxication, even if benzodiazepines are part of the polypharmacy overdose, as its use may increase the risk of status epilepticus, particularly in patients with a preexisting seizure disorder.

Hypotension occurring during phenytoin infusion is treated with discontinuation of the infusion and administration of crystalloid. Pressors are rarely necessary. Treatment of cardiac dysrhythmias is supportive, with use of the appropriate antidysrhythmics when indicated. Type IB antidysrhythmic agents should be avoided [17].

Patients with a seizure disorder should be placed on seizure precautions because of the possibility of paradoxical seizures during the acute intoxication phase or breakthrough seizures during the recovery phase when phenytoin levels may be in the subtherapeutic range. Seizures should be treated with benzodiazepines or a different anticonvulsant.

Because phenytoin has a long elimination half-life, measures to increase the rate of elimination should be considered. Gastrointestinal (GI) tract decontamination uses oral-activated charcoal administration. Phenytoin undergoes enterohepatic recirculation with active gut secretion; multiple-dose oral-activated charcoal (MDAC) can increase the rate of elimination and may decrease hospital stay [18] (see Chapter 97).

MDAC is indicated for patients with a phenytoin concentration greater than 40 μg per mL, moderate neurologic toxicity, or rising levels after GI tract decontamination. As drug levels may continue to decline for many hours after stopping MDAC, such therapy should be discontinued before drug levels reach the therapeutic range for patients who require phenytoin for therapeutic purposes. Serum levels of concurrent anticonvulsant medications may also decline when MDAC is administered, increasing the risk of breakthrough seizures. An observation period is necessary to ensure establishment of a therapeutic
anticonvulsant regimen and documentation of stable therapeutic serum levels even after passage of charcoal stools. Because phenytoin has a high degree of protein binding and hepatic elimination, forced diuresis, hemodialysis, and hemoperfusion are not useful and it is likely that hemofiltration would not be useful for similar reasons.

Disposition

Because the majority of patients with phenytoin poisoning do well with supportive therapy alone, determining the degree of toxicity is important. After adequate GI decontamination, the patient should be assessed for progression of toxicity. Patients who are not suicidal or ataxic, have no underlying cardiac dysrhythmias, can feed themselves, and are not at risk of hurting themselves can be discharged, providing serum phenytoin levels are not rising and a reliable caretaker is available. Patients who do not meet these criteria should be admitted. Severely toxic patients, those with an underlying cardiac or CNS disorder, intubated patients, or patients with rapidly progressive signs of toxicity require intensive care monitoring.
VALPROIC ACID

Valproic acid (VA; 2-propylpentanoic or 2-propyl valeric acid) is structurally unique among the anticonvulsants. VA is a branched-chain carboxylic acid with a $pK_a$ of 4.8. In addition to being an anticonvulsant medication, VA is commonly used for the treatment of acute manic episodes, mood stabilization, and prophylaxis of migraine and affective disorders.

VA is marketed as a sodium salt (Depakene); in a syrup solution; in a prodrug form, divalproex sodium (Depakote); and as a sustained-release form of divalproex sodium (Depakote ER). The latter is a molecular complex that dissociates in the GI tract into two molecules of VA. There is also a parenteral form for VA.

Pharmacology

VA is thought to mediate its anticonvulsant effect by increasing cerebral and cerebellar levels of GABA [19] by blocking its metabolism through inhibition of GABA transferase and succinic aldehyde dehydrogenase. It may also prolong the recovery of inactivated sodium channels and have effects on potassium channels in neuronal cell membranes.

The pharmacokinetic profile of VA is significantly altered in an overdose setting. Within its therapeutic range (50 to 100 mg per mL), VA is 80% to 95% serum protein bound [20]. The degree of protein binding decreases and the $V_d$ (0.13 to 0.22 L per kg) increases as VA levels exceed 90 $\mu$g per mL [20]. The resultant increase in free VA levels is evident by enhanced distribution into target organ systems and better than predicted extracorporeal drug removal. This has been demonstrated by a higher cerebrospinal fluid-to-serum level and hemodialysis extraction ratio in the VA-poisoned patient [21]. Protein binding of VA may also be decreased in uremic patients or in the presence of other highly protein-bound agents (e.g., acetylsalicylic acid), which displace VA from its binding sites.

VA is highly bioavailable, with the time to peak serum levels after ingestion dependent on the dosage form and VA species. In capsule form, VA itself achieves peak serum levels after 1 to 4 hours with therapeutic dosing, whereas peak serum levels may be delayed 4 to 5 hours after ingestion of the enteric-coated divalproex sodium tablets. Peak serum
levels may be delayed out to 17 hours with overdose [22]. This may be explained by the enteric-coating dissolution time and the sequential process of intestinal conversion of divalproex to the sodium salt. This is followed by the final conversion to the free acid, the only form absorbed from the GI tract. There is no evidence suggesting formation of pharmacobezoars from large numbers of VA tablets.

VA is metabolized predominantly by the liver, with 1% to 4% excreted unchanged in the urine [20]. It undergoes beta and omega oxidation to several metabolites: hydroxylvalproate, 2-propylglutarate, 2-propylpent-4-enoate, 5-hydroxyvalproate, and 4-hydroxyvalproate. At high doses of VA, the omega oxidation pathway may become saturated, leading to a decrease in total VA body clearance [21]. The metabolites undergo glucuronidation and biliary excretion, with a possible enterohepatic recirculation [21]. At therapeutic levels, VA elimination half-life averages 10.6 hours (range: 5 to 20 hours), but during an overdose it may extend to 30 hours.

VA disrupts amino acid and fatty acid metabolism, sequesters acetyl coenzyme A by forming valproyl coenzyme A, and interrupts the ornithine–citrulline shuttle and carnitine transport [23,24]. This may result in encephalopathy associated with hyperammonemia at therapeutic levels of VA [25], acutely contribute indirectly to the CNS depressant effects, and chronically contribute to other target organ toxicity. VA metabolites have been implicated in the metabolic perturbations associated with VA poisoning [25,26], interfere with urine ketone determinations, and may be the hepatotoxic mediators of VA. There may be a link between VA- and opiate-induced CNS toxicity because of their similar influence on the GABAnergic systems [11,27]. Because VA and its metabolites are low molecular weight, branched-chain carboxylic acids, they may be used as substrates for several enzymatic processes. This leads to inhibition of critical biochemical pathways, such as the urea cycle, and subsequent fatalities in some sensitive patient populations. Death has occurred after therapeutic doses of VA among patients with a congenital deficiency of ornithine carbamoyltransferase. In addition, a frequently fatal Reye-like hepatitis has been observed in patients receiving therapeutic doses. Those at greatest risk appear to be very young patients (younger than 2 years of age), those being treated with multiple anticonvulsants, and those with other long-term neurologic complications. The fatality rate is 1 per 500 in this patient population [28]. This hepatotoxic reaction occurs with chronic exposure and may be mediated by metabolites formed via the cytochrome P450 pathway. These metabolites in turn depress fatty acid oxidation in the hepatocyte mitochondria. This effect may parallel that seen after ingestion of ackee fruit containing hypoglycin, causing Jamaican vomiting sickness. VA can produce a hyperammonemia and
encephalopathy exclusive of the hepatotoxic reaction. This may be associated with VA-induced carnitine deficiency [25]. Valproate as the sodium salt provides a significant sodium load (13.8 mg sodium per 100 mg VA) in overdose. VA and its metabolites are low molecular weight, osmotically active, free acid, or anionic species. They may produce a slightly elevated osmolar gap and an elevated anion gap metabolic acidosis with a reduction in circulating endogenous cations, particularly calcium [21,23,29]. Valproate may have a dose-related toxic effect on bone marrow and platelet function, with resultant hematologic consequences such as thrombocytopenia, anemia, and leukopenia [30].

The morbidity and mortality from dose-related acute or acute-on-chronic VA poisoning appear to be related to hypoxic sequelae from respiratory failure, aspiration, or terminal cardiorespiratory arrest [21,29,31]. Although it has been speculated that VA has a direct, irreversible, neurotoxic effect, this has not been substantiated and it is indistinguishable from hypoxic injury.

Patients ingesting greater than 200 mg per kg are at high risk of significant CNS depression, but poor correlation exists between peak serum level and dose of VA ingested [31]. Patients who die from acute VA poisoning have had peak serum VA levels ranging from 106 to 2,728 μg per mL, whereas survival has been reported in a patient with a peak serum level of 2,120 μg per mL [23]. Although serum VA levels may not correlate with clinical effects, in general, serum levels of 180 μg per mL are usually associated with serious CNS toxicity (e.g., coma and apnea) and significant metabolic derangements (e.g., acidosis and hypocalcemia) [23,32]. The duration of toxicity is proportional to the peak serum VA level.

On the basis of endogenous VA clearance, it will take 3 days for the serum level to drop within the therapeutic range for a patient with a serum level greater than 1,000 μg per mL.

Clinical Manifestations

During acute intoxication, hypotension, mild tachycardia, decreased respiratory rate, and elevated or depressed temperature may be seen. Miosis may be present. The hallmarks of VA toxicity are global CNS-related depression in conjunction with unique metabolic changes. The mental status varies on a continuum from confusion and disorientation to obtundation and deep coma with respiratory failure. Tremor, hallucinations, and hyperactivity have been reported, but there is a notable lack of cerebellar–vestibular effects. Patients with an underlying seizure disorder may have breakthrough seizures. Most patients with serious acute VA poisoning manifest CNS toxicity for at least 24 hours and this may extend to several days. Laboratory abnormalities observed
among patients with high serum VA levels include an anion gap metabolic acidosis, hypocalcemia, hyperosmolality, and hypernatremia. Transient rises in serum transaminase levels have been observed without evidence of functional liver toxicity. Hyperammonemia associated with vomiting, lethargy, and encephalopathy may occur at therapeutic serum levels. Although rare, complications or delayed sequelae associated with severe VA intoxication include optic nerve atrophy, cerebral edema, acute respiratory distress syndrome, and hemorrhagic pancreatitis.

Non–dose-related toxicities include hepatic failure, pancreatitis, red blood cell aplasia, neutropenia, and alopecia. Pancreatitis is usually considered a non–dose-related effect but has been observed. Alopecia, thrombocytopenia, leukopenia, and anemia have been associated with acute and chronic VA intoxication.

The differential diagnosis should include opioid toxicity and a list of substances causing an increased anion gap metabolic acidosis. VA intoxication can be indistinguishable from opioid poisoning by signs and symptoms, and VA-poisoned patients may occasionally respond to naloxone. VA may cause a false-positive urine ketone determination, thereby misdirecting the clinician to causes of ketosis [23].

**Diagnostic Evaluation**

Essential laboratory studies should include sequential serum VA levels and levels of other anticonvulsant medications, particularly when the enteric-coated dosage form is involved. It should be recognized that VA metabolites are highly cross-reactive on enzyme-multiplied immunoassay technique assay for VA [21], and there may be an overestimation of serum VA levels as high as 50%. Recommended laboratory studies include complete blood cell count, reticulocyte count, serum electrolytes, blood urea nitrogen, creatinine, glucose, calcium, ammonia, and liver function tests. In addition, serum amylase and lipase levels should be obtained to rule out pancreatitis.

In all deliberate overdoses, an ECG and acetaminophen and salicylate levels should be obtained. Arterial blood gas, chest radiograph, head computed tomography, and lumbar puncture should be obtained when clinically indicated.

**Management**

As with any consequential CNS depressant ingestion, the patient’s airway
and respiratory status should be frequently assessed; early intubation and ventilation help prevent hypoxic sequelae. Vascular access and continuous cardiac monitoring should be established. Patients with altered mental status should have a fingerstick blood sugar determination or receive IV dextrose, followed by naloxone and thiamine as clinically indicated.

Naloxone (0.8 to 2.0 mg) has been reported to be effective in increasing the level of consciousness of patients with signs and symptoms of opioid toxicity and serum VA levels between 185 and 190 μg per mL [32]. Patients with higher VA serum levels have not responded to larger doses of naloxone [33]. Naloxone has been shown experimentally to antagonize GABA, the inhibitory neurotransmitter increased by VA [11,27]. It is therefore worth trying naloxone (up to 10 mg) for all comatose patients with suspected VA poisoning. Flumazenil, the benzodiazepine antagonist, should be avoided for patients with a preexisting seizure disorder.

Carnitine has been used for the treatment of hyperammonemia because VA interferes with the citrulline–ornithine cycle and carnitine’s availability to shuttle fatty acids across the mitochondrial membrane. There are some pediatric data suggesting that carnitine may improve mental status [24,34]. The oral and parenteral carnitine doses range from 1.5 to 2.0 g, divided into three to four doses per day.

GI decontamination should be performed for patients with suspected VA, even if several hours have elapsed since ingestion [35]. Activated charcoal is preferred; gastric lavage and whole-bowel irrigation for enteric-coated preparations are additional options. Methods to enhance elimination may be effective as an increase in the free serum drug fraction, decreased protein binding, and marked prolongation in elimination half-life occur after overdose. MDAC may enhance the clearance and reduce the VA half-life by interrupting enterohepatic recirculation and GI tract dialysis [36]. Extracorporeal removal by hemodialysis or hemoperfusion is also effective. Indications for extracorporeal removal are not clearly defined, requiring a risk–benefit analysis on a case-by-case basis. It should be considered when the VA level exceeds 1,000 μg per mL and is recommended for patients with levels exceeding 2,000 μg per mL. In a patient with a level exceeding 2,000 μg per mL, prompt institution of hemodialysis led to complete resolution of toxicity within 3 days, whereas a similar patient managed with only supportive care died [23]. Patients not responding to conventional therapy or who have severe acid–base derangement may also benefit from hemodialysis. VA clearance during hemodialysis has been as high as 270 mL per minute, with a four- to fivefold decrease in elimination half-life. Hemodialysis has the added benefit of correcting acid–base derangements secondary to VA and removal of its metabolites.
Because of VA’s extensive protein binding and predominate hepatic elimination, it is anticipated that forced diuresis, manipulation of urine pH, and hemofiltration would not be useful in the management of VA intoxication. Charcoal hemoperfusion used for VA intoxication has demonstrated clearance similar to that of hemodialysis [28]. Use of hemodialysis and hemoperfusion in series may be more advantageous because of a more consistent extraction of VA as its degree of protein binding increases coincident with declining levels and desaturation of binding sites [37].

Disposition

The disposition of the VA-poisoned patient is based on the severity of CNS toxicity, quantitative serum levels, evidence of hypoxic insult, risk of secondary complications, and the amount of VA ingested. Patients with serum VA levels exceeding 150 μg per mL are at risk of CNS and respiratory depression and should be observed until levels return to the therapeutic range. Patients with VA serum levels exceeding 1,000 μg per mL are at high risk of serious prolonged toxicity and should be admitted to an intensive care unit.
CARBAMAZEPINE

CBZ is an iminostilbene compound with a chemical structural backbone resembling that of the tricyclic antidepressants. It is stereochemically similar to phenytoin. CBZ has long been recognized as a well-tolerated and effective agent for the management of various types of seizure disorders. It is also used for the treatment of trigeminal and glossopharyngeal neuralgias, tabetic pain, and affective disorders [38]. A sustained-release formulation is available.

Pharmacology

Because CBZ is unionized and highly lipophilic, there is no parenteral dosage form, and the rate-limiting step for systemic absorption is tablet dissolution time. Consequently, the pharmacokinetics and toxicokinetics of CBZ are not well defined and are subject to significant inter- and intrapatient variability. CBZ is 80% protein bound and may have twice the $V_d$ of other anticonvulsants, such as phenytoin and phenobarbital.

In overdose, systemic absorption of CBZ may be inconsistent over time. This leads to intermittent surges of drug released into the circulation and may cause unexpected clinical deterioration of patients. This may explain the “cyclic coma” associated with CBZ poisoning [39]. Patients have been reported to relapse into deep coma as late as 2 days after admission to the hospital coincident with a marked increase in plasma levels of CBZ, even after the patient’s condition has appeared to stabilize or improve clinically. CBZ’s $V_d$ ranges from 1.4 to 3.0 L per kg at toxic levels [40].

CBZ is predominantly metabolized in the liver, with 1% to 3% excreted unchanged in the urine. Endogenous clearance is 0.6 to 1.3 mL/kg/min [38]. The variability in clearance may be attributed to alteration in the metabolic capabilities of hepatic enzymes, particularly the cytochrome P450 system [38]. This system is sensitive to autoinduction during chronic administration or, conversely, inhibition with concurrent administration of enzyme inhibitors such as erythromycin [41]. The elimination half-life of CBZ in naive users may exceed 24 hours, whereas in chronic users it may be less than 15 hours [38, 42]. Half-life determinations of CBZ, especially during an overdose, often are misleading because of erratic absorption and inability to determine the
contribution of sustained absorption from the GI tract [42]. Most evidence suggests that CBZ undergoes first-order kinetics, although it is postulated that some of its metabolic pathways, such as epoxidation, may follow Michaelis–Menten kinetics and saturate at high levels [42].

Forty percent of CBZ is converted to the active metabolite CBZ-10,11-epoxide (CBZ-epoxide), further complicating the kinetic and toxicity profile of CBZ [38]. An inactive metabolite is also formed. CBZ-epoxide elimination half-life is 5.0 to 9.8 hours and is in turn converted to 10,11-dihydroxide [40,42]. CBZ-epoxide is much less protein bound than CBZ (50% vs. 80%) [38]. The therapeutic CBZ concentration is 3 to 14 μg per mL. Within this range, adverse drug events including nystagmus, ataxia, dizziness, and anorexia have been noted [43].

CBZ may be best described as a CNS depressant with mild anticholinergic activity and a proclivity for alteration in the cerebellar–vestibular brainstem function. CBZ mediates its pharmacologic effects by mechanisms that include stabilizing the inactive sodium channel, alteration in neurotransmitter activity (norepinephrine, acetylcholine), enhancement of adenosine, stimulation of benzodiazepine receptors, and depression of evoked repetitive firings in neurons and the brainstem reticular formation [38].

CBZ has been described as similar to tricyclic antidepressants in its toxicity profile [39,44,45]. Although these agents share sedative, anticholinergic, and sodium channel blocking activity, CBZ has a higher therapeutic index, and malignant cardiac dysrhythmias and seizures do not usually occur among patients with normal cardiac and neurologic function. During overdose with extremely high CBZ levels, however, fatal dysrhythmias may develop [43,46].

CBZ toxicity can be defined as dose dependent or non–dose dependent. Non–dose-dependent toxicity includes idiosyncratic and immunologic-mediated reactions such as bone marrow suppression, hepatitis, tubulointerstitial renal disease, cardiomyopathy, hyponatremia, and exfoliative dermatitis. Dose-related effects for sensitive populations include those with existing neurologic deficits and myocardial disease. Dose-related toxicity has been reported for acute overdoses, with survival of adults after 80-g ingestions. Death has been reported after acute ingestion of 60 g and after a 6-g ingestion by a patient receiving long-term maintenance therapy [45,47].

Respiratory depression and significant neurologic toxicity and death have been reported, with peak serum CBZ levels ranging from 20 to 65 μg per mL [39,40,43,45,47–51]. Patients with serum levels in the range of 10 to 20 μg per mL usually respond to verbal stimuli unless other coexisting medical complications or additional sedative–hypnotic substances are present [43].

There is poor correlation of serum CBZ levels with clinical outcomes.
Prognosis appears to depend on the occurrence of respiratory depression and aspiration of gastric contents [43, 45, 47–52]. All reported deaths occurred among patients with a history of seizure disorders. Surviving patients may have a protracted course (days to weeks) because of secondary complications arising from hypoxic-related sequelae from respiratory and CNS depression, prolonged GI tract absorption, and a prolonged elimination half-life.

The kinetics of CBZ toxicity are affected by the active metabolite CBZ-epoxide, which may partially account for the lack of correlation between peak CBZ levels and the severity of symptoms. The concentration of CBZ-epoxide is only 40% that of CBZ; however, CBZ-epoxide concentration in the free, unbound form may be equal to or greater than that of CBZ [53].

Toxicity may occur by gradual accumulation of CBZ among patients receiving therapeutic dosing because of improper dosing protocols or as a result of a drug interaction with enzyme inhibitors such as erythromycin or verapamil [41] or from generic substitution [54].

Clinical Manifestations

Patients with acute and chronic exposures have similar findings. Key findings suggestive of CBZ poisoning include the triad of coma, anticholinergic syndrome, and adventitious movements. Physical findings include CNS depression with pronounced effects on the cerebellar–vestibular system (e.g., nystagmus, ataxia, ophthalmoplegia, diplopia, absent doll’s eye reflex, and absent caloric reflexes), central and peripheral anticholinergic toxicity (e.g., hyperthermia, sinus tachycardia, hypertension, urinary retention, mydriasis, and ileus), and neuroleptic-type movement disorders (e.g., oculogyric crisis, dystonia, opisthotonus, choreoathetosis, and ballismus), which can occur in patients without preexisting neurologic disorders.

Other effects, which are not clearly reproducible and may be indirectly related to hypoxia or occur in patients with preexisting disease, include cardiac conduction disturbances, hypotension, hypothermia, respiratory depression, deep coma, diminished or exaggerated deep tendon reflexes, and dysarthria. Some patients may be agitated and restless, combative, or irritable, experience hallucinations, or have seizures. Because CBZ has prolonged absorption from the GI tract and prolonged elimination half-life, the clinical course may be extremely protracted and deceptive, and sudden deterioration may occur days after admission [39].

Seizures associated with high levels of CBZ appear to occur predominantly in patients with preexisting neurologic disorders. In many reports, it is unclear whether witnessed motor activity was a true seizure or another movement disorder and whether the seizure occurred primarily or was secondary to hypoxic insult [39, 43, 44, 53].
Cardiac conduction disturbances such as prolongation of the PR, QRS, and QTC intervals and complete heart block have been reported [55]. Patients with an underlying abnormal cardiac conduction system may be at particular risk for the development of complete heart block [56]. For most patients, conduction defects are not seen or there is marginal prolongation of intervals without progression to malignant dysrhythmia despite extremely high CBZ levels [44,45,57].

Diagnostic Evaluation

Essential laboratory studies should include sequential serum CBZ levels and levels of other anticonvulsant medications, serum electrolytes, blood urea nitrogen, creatinine, and ECG. Recommended laboratory studies include complete blood cell count and liver function tests. For all deliberate overdoses, acetaminophen and salicylate levels should be obtained. Arterial blood gas, chest radiograph, head computed tomography, and lumbar puncture should be obtained as clinically indicated.

CBZ and CBZ-epoxide are highly cross-reactive on enzyme-multiplied immunoassay technique assays for CBZ and can result in a falsely elevated CBZ level. The clinical consequence of this is debatable, however. High-pressure liquid chromatography assay has the ability to distinguish between CBZ and CBZ-epoxide. Using the ratio of CBZ to CBZ-epoxide, an index can be generated that may reflect the rapidity of absorption of CBZ from the GI tract. A ratio greater than 2.5 is evidence of rapid or continued CBZ absorption from the GI tract. Cases in which patients appear to relapse or deteriorate may be due to an abrupt increase in absorption occurring as late as 48 hours after the initial ingestion [45,51]. For cases in which serial CBZ and CBZ-epoxide levels were monitored, the ratio greatly increased just before and coincident with the clinical deterioration [39].

Patients whose serum CBZ level continues to significantly rise, manifesting delayed symptoms, or who appear to relapse or deteriorate after appropriate GI decontamination should be suspect for harboring pharmacobezoars in their GI tract. Radiographic contrast study should be considered to confirm this diagnosis; CBZ is not radiopaque [57]. The differential diagnosis of CBZ toxicity includes tricyclic antidepressants, neuroleptics, sedative–hypnotics, anticholinergic agents, and other anticonvulsant poisonings.
Management

Management begins with treatment of respiratory, neurologic, and cardiovascular derangements. Early intubation and ventilation should be considered, as poor outcomes with CBZ-poisoned patients are primarily associated with pulmonary complications. Vascular access and continuous cardiac monitoring [38,39,43] should be established. Hypotension should be initially managed with crystalloid fluid challenges followed by pressor agents [39,45]. There is no specific antidysrhythmic regimen for CBZ-induced cardiac toxicity. IV sodium bicarbonate therapy should be considered for patients whose QRS is greater than 100 ms. Patients with altered mental status should have a fingerstick blood sugar determination or receive IV dextrose, followed by naloxone and thiamine as clinically indicated. Seizures are usually self-limited but respond to IV diazepam or phenytoin [40].

GI decontamination should be initiated as soon as possible with activated charcoal. MDAC may double the elimination of systematically absorbed CBZ [58] (see Chapter 97) and should also be considered for patients with serum CBZ concentration greater than 20 μg per mL. MDAC should be discontinued before CBZ levels decline to the therapeutic range for those with an underlying seizure disorder. Although MDAC therapy significantly reduces serum CBZ levels, it has not been shown to improve patient outcomes [59]. For patients with rising drug levels despite initial GI tract decontamination, whole-bowel irrigation may also be useful (see Chapter 125).

Hemoperfusion has been used to enhance CBZ clearance in overdose cases but with modest results, usually no more than the increase achieved by MDAC, which is less invasive [45,48]. In one case, it was equivalent to an increase in CBZ excretion of 200 mg per hour [45]. If used at all, extracorporeal removal should be reserved for those with greatly elevated serum levels and concomitant deep coma. Neither urinary manipulation nor hemodialysis is useful.

Although there is one case report of a CBZ-poisoned patient (serum level: 27.8 μg per mL) who responded to a dose of flumazenil [50], this agent may precipitate seizures and is contraindicated for CBZ overdose. Physostigmine has been reported to be effective in the treatment of dystonia associated with CBZ poisoning [44]. Given that CBZ-associated dystonias are self-limited, the risks of physostigmine therapy likely outweigh its potential benefits.

Disposition

Because CBZ displays erratic absorption, the decision should be in favor of admission and a prolonged observation period in an intensive care
setting for patients with a history suggestive of a large ingestion. CBZ-poisoned patients at greatest risk of significant sequelae should also be admitted to the intensive care unit. This would include patients whose CBZ levels exceed 20 $\mu$g per mL or are rapidly rising, who are obtunded or comatose, those with cardiovascular symptoms, whose ECG shows a QRS greater than 100 ms, and those with seizures. The majority of patients at risk of significant sequelae require observation for a minimum of 48 hours.
NEWER ANTICONVULSANTS

Felbamate (Felbatol)

Felbamate is a phenyl dicarbamate with a structure similar to that of the sedative–hypnotic agent meprobamate. Its mechanism of action is believed to have some indirect effect on the GABA_A-receptor supramolecular complex [60], block repetitive neuronal firing, and affect the sodium channel of the neuronal membrane. Felbamate is rapidly absorbed, with a bioavailability of 90% and peak plasma concentrations occurring 1 to 4 hours after oral dosing. Its $V_d$ is 0.75 L per kg. The drug circulates as the free drug and is only 20% to 30% protein bound. Absorption and elimination are linear and plateau at high levels. The drug undergoes partial hepatic metabolism with an inactive metabolite and renal excretion. Approximately 40% of a dose is eliminated unchanged in the urine. The elimination half-life is 20 to 23 hours. Felbamate does not induce its own metabolism [61].

Felbamate has significant drug interactions. It can inhibit and induce the cytochrome P450 system. This affects the metabolism of coadministered medications. Felbamate induces the metabolism of CBZ and inhibits the metabolism of phenytoin and VA. The effect of felbamate on metabolism takes 2 to 3 weeks to clear after discontinuation of the drug [61].

Although uncommon, serious adverse drug events include aplastic anemia and hepatic failure, which is associated with a 20% mortality rate. Other adverse drug events include nausea, vomiting, abdominal pains, headache, insomnia, palpitations, tachycardia, blurred vision, diplopia, tremors, and ataxia. Children are likely to demonstrate anorexia and somnolence [61].

There is limited information regarding deliberate felbamate overdose. A 20-year-old woman developed altered mental status, massive crystalluria, and acute renal failure after an overdose of felbamate and VA. Macroscopic urinary crystals were identified by gas chromatography as containing felbamate. Crystalluria and acute renal failure resolved with hydration. A 44-year-old man who ingested an unknown amount of felbamate, haloperidol, and benztropine recovered with supportive care. Symptoms were predominately neurologic, with ataxia, nystagmus, weakness, abnormal movements, and agitation [62]. The management of felbamate overdose is supportive care. Gut decontamination with activated charcoal would appear to be reasonable. There are no data on hemodialysis, hemoperfusion, or urinary manipulation [62].
Lamotrigine (Lamictal)

LTG, or 3–5-diamino-6 (2,3-dichlorophenyl)-1,2,4-triazine, is not structurally related to other anticonvulsants. The mechanism of action of LTG is believed to involve voltage-sensitive sodium channels and stabilizes neuronal membranes. Lamotrigine has no effect on the release of GABA, acetylcholine, norepinephrine, or dopamine. In oral dosing, LTG is rapidly absorbed, with a bioavailability of 98%. Peak plasma levels are reached 1 to 4 hours after dosing. Protein binding is 55%, and the $V_d$ ranges from 0.9 to 1.4 L per kg. LTG is metabolized in the liver and excreted as the glucuronide metabolite. LTG does not induce its own metabolism. The elimination half-life of the parent compound is 12 to 50 hours (mean: 30 hours) [61].

Adverse drug events include Stevens–Johnson syndrome, toxic epidermal necrolysis, drowsiness, dizziness, headache, unsteady gait, tremor, ataxia, somnolence, diplopia, blurred vision, and nausea [61]. There is increasing information regarding deliberate LTG overdose [63,64]. One patient presented with nystagmus and ataxia 1 hour after ingestion. The initial ECG showed a normal sinus rhythm with a QRS of 112 ms, which gradually resolved over 48 hours. In another case, ataxia, rotary nystagmus, and a normal ECG were noted. A 2-year-old boy developed tremor, muscle weakness, ataxia, hypertonia, and generalized tonic–clonic seizure after ingesting 800 mg of LTG.

The management of acute LTG overdose should include GI decontamination, continuous cardiac monitoring, and supportive care. It would be prudent to closely monitor a patient with serial ECGs for 24 to 48 hours if the initial ECG shows a prolonged QRS duration (greater than 100 ms). IV sodium bicarbonate therapy has not been studied but should be considered. Benzodiazepines are appropriate for the treatment of seizures. There are no data on hemodialysis or hemoperfusion.

Gabapentin (Neurontin)

GBP is an engineered molecule based on GABA and altered to increase membrane permeability and entrance through the blood–brain barrier. Chemically, GBP is GABA with a cyclohexane ring (1-[aminomethyl]-cyclohexane) [61].

Gabapentin appears to bind to a specific site in the CNS but does not affect ligand binding to $\text{GABA}_A$, $\text{GABA}_B$, benzodiazepine, glutamate,
glycine, and N-methyl-D-aspartate sites on the neuronal membrane [61].

GBP is 50% to 60% absorbed from the GI tract, with peak serum levels occurring 1 to 3 hours after oral administration. Its $V_d$ is 0.8 to 1.0 L per kg. GBP is not protein bound and does not appear to be metabolized; all of a dose is excreted unchanged in the urine. The terminal elimination half-life is 5 to 7 hours. Renal elimination and half-life are proportional to renal function. The elimination rate can neither be induced, nor can the elimination half-life be altered with repetitive dosing [61].

Adverse drug events include CNS depression, nystagmus, blurred vision, diplopia, mood changes, headache, weight gain, seizures, fatigue, nausea, dizziness, slurred speech, and unsteady gait. Lethargy, somnolence, dizziness, drowsiness, dysarthria, diplopia, sedation, ataxia, slurred speech, and GI distress have been observed after overdose [65,66]. Signs and symptoms resolved within 48 hours without specific therapy. Treatment is supportive. There are no data on binding to activated charcoal, urinary manipulation, hemodialysis, or hemoperfusion.

**Oxcarbazepine (Trileptal)**

Oxcarbazepine is the dihydro derivative of CBZ and can be thought of as being a prodrug, which is almost 100% biotransformed during hepatic first-pass metabolism to the active metabolite 10,11-dihydro-10-hydroxycarbamazepine. It has the same anticonvulsant effect as CBZ. The parent and the metabolite are lipophilic and pass into the CNS. Its advantages are that it has better tolerability and does not form the CBZ-epoxide. Peak serum drug levels occur 4.5 hours after an oral dose. The $V_d$ is 49 L per kg. The elimination half-lives of oxcarbazepine and its metabolite are 1.0 to 2.5 hours and 8 to 11 hours, respectively. Adverse drug events include hyponatremia (in up to 30% of patients), headache, ataxia, dizziness, nausea, memory impairment, concentration difficulties, anorexia, and weight gain [67]. Evaluation and treatment considerations are the same as for CBZ. CBZ assays cannot be used to measure oxcarbazepine levels. Oxcarbazepine concentrations are not routinely available and are generally not useful for patient management.

**Tiagabine (Gabitril)**

Tiagabine is a GABA reuptake inhibitor derived from nipecotic acid to which a lipophilic moiety has been added to improve passage into the CNS. By selectively inhibiting neuronal GABA reuptake, it prolongs the action of GABA in the synapse. It is rapidly absorbed orally, with a peak level by 0.5 to 1.0 hours after ingestion. The drug is 96% protein bound and is metabolized by the CYP3A4 isoform to inactive metabolites. There
is some degree of enterohepatic circulation. The elimination half-life ranges from 4 to 7 hours in patients receiving enzyme-inducing drugs. Adverse drug events include CNS depression, nausea, hypertension, tachycardia, asthenia, sedation, dizziness, mild memory impairment, abdominal pain, and nausea. Some patients develop status epilepticus after overdose. Symptoms typically resolve within 12 to 24 hours [68]. Treatment is supportive.

Topiramate (Topamax)

Topiramate is a sulfamate-substituted monosaccharide compound different from other anticonvulsants. Its mechanism of action may be in part due to sodium channel blockade, enhancing the action of GABA, and diminishing kainate-induced excitatory receptor stimulation. Oral absorption is rapid, with a peak serum level at 1.8 to 4.3 hours. The plasma protein binding of topiramate is 9% to 17%, and its $V_d$ is 0.7 L per kg. It is 70% to 97% eliminated unchanged in the urine. The elimination half-life is 18 to 24 hours.

Development of a nonanion-gap metabolic acidosis is a relative common occurrence with topiramate use, both in therapeutic dosing and in overdose [69]. This occurs by impairing both the normal reabsorption of filtered bicarbonate by the proximal renal tubule and the excretion of hydrogen ions by the distal renal tubule. This combination of defects is termed mixed renal tubular acidosis [70]. Treatment of the metabolic acidosis includes cessation of the topiramate and fluid resuscitation as needed. The use of parenteral sodium bicarbonate is rarely needed. Other adverse drug events include sedation, cognitive dysfunction, paresthesias, dizziness, fatigue, weight loss, diarrhea, and urolithiasis. Treatment is supportive.

Levetiracetam (Keppra)

Levetiracetam (Keppra) is a newer anticonvulsant that is now used nearly as often as phenytoin. Although its precise mechanism of action is unknown, levetiracetam does not appear to directly interact with the GABA system. The most common adverse effects in overdose are sedation, vertigo, and ataxia, although respiratory depression may also occur [71]. Therapeutic concentrations of levetiracetam are generally considered to be 10 to 40 μg per mL, but because its therapeutic window is so large, monitoring of blood concentrations is generally not performed. There is no specific antidotal therapy for levetiracetam overdose. Treatment is supportive care.

Vigabatrin (Sabril)
Vigabatrin is an engineered GABA-related anticonvulsant with limited availability in the United States. Chemically, it is gamma-vinyl-GABA. It is a stereospecific GABA transaminase inhibitor, the S(+) enantiomer being biologically active. Its peak serum level occurs 0.5 to 3.0 hours after ingestion, and its $V_d$ is 0.8 L per kg. There is virtually no plasma protein binding of the drug, and more than 80% of the drug is eliminated unchanged. The plasma half-life ranges from 4 to 8 hours. The cerebrospinal fluid level is 0% to 15% of the serum level [65]. Adverse drug events include visual field defects, diplopia, drowsiness, irritability, agitation, anxiety, psychomotor effects, depression, sedation, confusion, and ataxia. A patient who ingested 8 to 12 g in an overdose developed a psychotic episode lasting 36 hours. Supportive care is the mainstay of management.

7. Denning DW, Matheson L, Bryson SM, et al: Death due to

Antidepressants comprise a group of substances primarily indicated in the treatment of major depression. However, since their development in the 20th century, FDA-approved indications for the use of antidepressants for psychiatric and nonpsychiatric illnesses have greatly expanded and so has their consumption. Some indications for the use of cyclic antidepressants (CAs) include treatment of depression, therapy of enuresis in children, treatment of migraine headaches, chronic pain control, smoking cessation, panic disorders, premenstrual dysphoric syndrome, and cocaine detoxification \[1,2\]. The Center for Disease Control, based on data collected via the National Health and Nutrition Examination Surveys, estimates that approximately 1 in 10 Americans over the age of 12 take antidepressant medications \[3\]. Given the numerous prescriptions for antidepressants, these medications are freely available to patients who are at high risk for suicide or overdose. The consequences of overdose are severe and predominantly affect the central nervous system (CNS) and cardiovascular system. In 2014, there were over 110,000 antidepressant exposures reported to US poison control centers that resulted in more than 8,600 moderate or major outcomes and 32 deaths \[4\].

HISTORY

Although the first antidepressants were synthesized in the late 19th century as iminodibenzyl, the pharmacology of CAs was not detailed until the 1940s. These compounds were initially designed to have antihistaminic, sedative, analgesic, and antiparkinsonian properties. Imipramine (Tofranil), the first of the dibenzazepines, was synthesized as a phenothiazine derivative in the late 1950s, but was found to be
ineffective as a neuroleptic agent. Patients taking imipramine reported having mood-elevating effects; hence, imipramine and later congeners became the mainstay in the treatment of endogenous depression. As their use increased, the toxicity of CA became more relevant in overdose. In the 1980s, newer generations of CAs were developed in hopes to eliminate some of the adverse effects. These include the tetracyclic antidepressants (e.g., mirtazapine) and the atypical antidepressants (e.g., bupropion). More recently, a newer class of antidepressants called selective serotonin reuptake inhibitors (SSRIs) have been developed followed by the serotonin–norepinephrine reuptake inhibitors (SNRIs) agents.

Monoamine oxidase inhibitors (MAOIs) were first used clinically in the mid 1950s but became popular as first-line therapy for depression as late as the 1970s. Iproniazid was first developed as an antituberculosis medication but after its antidepressant effects were noted, it became the first antidepressant used clinically in the 1950s. Although they remain potent and effective medications, their many food and drug interactions have limited their use so that reports of toxic exposures are becoming much less common.
TYPES OF ANTIDEPRESSANTS

Antidepressants are generally grouped by their mechanism of action or chemical structure. The most common categories include CAs, SSRIs, SNRIs, norepinephrine reuptake inhibitors (NRIs), MAOIs, and lithium salts. Classic tricyclic antidepressants have a seven-membered central ring with a terminal nitrogen containing either three constituents (tertiary amines) or two constituents (secondary amines) [5]. Tertiary amines include amitriptyline, imipramine, doxepin, trimipramine, and chlorimipramine (clomipramine). Secondary amines include desipramine, protriptyline, and nortriptyline. Included with CAs are two dibenzoxazepine compounds that contain the central seven-membered ring with a heterocyclic constituent: loxapine and its demethylated metabolite amoxapine.

Maprotiline, a dibenzobicyclooctadiene, mianserin, and mirtazapine (Remeron) are tetracyclic antidepressants [6,7]. Mirtazapine, a derivative of mianserin, has additional α₂-antagonist activity. Bicyclic compounds include viloxazine, venlafaxine, and zimeldine.

CAs that are not available in the USA because of side effects include mianserin (agranulocytosis), nomifensine (hepatotoxicity and hemolytic anemia), lofepramine (hepatotoxicity and hyponatremia), and zimeldine (Guillain-Barré syndrome) [13–15].

Selective serotonin reuptake inhibitors include fluoxetine, paroxetine, sertraline; fluvoxamine; citalopram; and scitalopram and have various chemical structures. Trazodone, nefazodone, and vilazodone are serotonin antagonist and reuptake inhibitors that are riazolopyridine derivatives. They are structurally and pharmacologically different from the other antidepressants. Similarly, vortioxetine is a new serotonergic agent that acts via inhibiting serotonin reuptake as well as showing mixed antagonist and agonist effects at various serotonin receptors [12].

Bupropion is a unicyclic phenylethylaminoketone classified as a norepinephrine and dopamine reuptake inhibitor (NDRI) [8,9].

Venlafaxine and duloxetine are considered SNRIs since they have norepinephrine reuptake inhibition effects. Desvenlafaxine is the major active metabolite of venlafaxine [10]. Levomilnacipran is the more active enantiomer of milnacipran, which is approved in Europe and Japan, and has relatively greater norepinephrine uptake compared to serotonin [11]. Although not classically considered SSRIs, some antidepressant agents that have serotonergic activity include mirtazapine, trazodone, nefazodone, and clomipramine. Vortioxetine is a new serotonergic agent that acts via inhibiting serotonin reuptake as well as showing mixed antagonist and agonist effects at various serotonin receptors [12].
The MAOIs are a third class of antidepressants and include moclobemide, pargyline, phenelzine, tranylcypromine, selegiline, and isocarboxazid. They are used to treat depression, panic disorders, phobias, and obsessive-compulsive behavior. A group of MAOIs that selectively inhibit the monoamine oxidase (MAO) isoenzyme type B (MAO-B) are being used as agents to treat Parkinson’s disease [16].
PHARMACOLOGY

TCAs

The CAs act as neurotransmitter postsynaptic receptor blockers for histamine, dopamine, acetylcholine, serotonin, and norepinephrine (NE). They inhibit the reuptake of neurotransmitter biogenic amines and have quinidine-like membrane-stabilizing effects [2, 6, 7, 13, 17, 18] (Tables 104.1–104.3). These agents may induce atrioventricular blocks [19, 20] and have direct negative cardiac inotropic effect, demonstrated by decrease in the rate of change in left ventricular pressure and an increase in left ventricular end-diastolic pressure [21, 22]. CNS effects may be related to both neurotransmitter and direct membrane effects [23–26]. All tricyclic antidepressants increase the density of β adrenoreceptors.

SSRIs and SSNRIs alter serotonergic neurotransmission. The International Union of Pharmacological Societies Commission on Serotonin Nomenclature has classified at least 14 5-hydroxytryptamine (5-HT) receptors based on operational criteria (Table 104.4). SSRIs block some serotonin receptors and inhibit the reuptake of serotonin at other receptor subtypes. Buspirone, a nonbenzodiazepine sedative-hypnotic, is a 5-HT$_{1A}$ partial agonist and is inhibitory on serotonin neuronal firing [27]. It has anxiolytic and antidepressant activity. Excessive stimulation can lead to hypotension. Antagonists at 5-HT$_{1C}$, such as ritanserin, may be anxiolytic. The 5-HT$_{1D}$ receptor subtype stimulation leads to inhibition
of neurotransmitter release, and the representative agonist is sumatriptan, an antimigraine medication. Stimulation at 5-HT\textsubscript{2} can cause vasoconstriction, and 5-HT\textsubscript{3} antagonists have antiemetic and antipsychotic activity (ondansetron) [27–29]. Classic tricyclic antidepressants affect serotonin neurotransmission by enhancing the sensitivity of 5-HT\textsubscript{1A} postsynaptic receptors. The SSRIs alter the release of serotonin presynaptically, leading to an increase in the amount of serotonin that is available for neurotransmission without changing the sensitivity of the 5-HT\textsubscript{1A} postsynaptic receptors [30]. In general, the SSRIs normalize the number and function of 5-HT\textsubscript{1A} and 5-HT\textsubscript{2} receptors [28,29]. As a group, the predominant difference between SSRIs is in their effect on the hepatic cytochrome P450 system and drug–drug interactions.

Venlafaxine and duloxetine are considered selective serotonergic and NE reuptake inhibitors. Blockade of NE-α₂ receptors leads to decrease in 5-HT release. Selective serotonergic and NE reuptake inhibitors induce desensitization and downregulation of 5-HT and NE receptors, leading to disinhibition of serotonergic neurons, interruption of feedback inhibition, and increased release of synaptic 5-HT.

MAOIs inhibit the activity of MAO, a flavin-containing enzyme located in the mitochondrial membranes of most tissues [31]. MAO enzymes are divided into two families: MAO-A, which uses 5-HT as its predominant substrate, and MAO-B, whose primary substrates include 2-phenylethylamine and O-tyramine. Monoaminergic neurons contain predominantly MAO-A; serotonergic neurons have both. MAO-A metabolizes epinephrine, NE, metanephrine, and 5-HT. MAO-A and MAO-B both metabolize tyramine, octopamine, and tryptamine [32]. MAO regulates intraneuronal catecholamine metabolism and mediates the oxidative deamination of epinephrine, NE, dopamine, and 5-HT. MAO also regulates ingested monoamine (tyramine, ethanolamine) in the gut that would normally be absorbed into the portal circulation [33,34]. The effect of MAOs is to increase the catecholamine storage pool by preventing intraneuronal degradation of catecholamines and 5-HT. These
catecholamines can be released by indirectly acting sympathomimetic agents (e.g., amphetamine, tyramine, and dopamine). MAO-A is predominantly found in the intestinal mucosa, placenta, biogenic nerve terminals, liver, and brain; whereas MAO-B is found in the brain, platelets, and liver [35]. Exogenously administered catecholamines are metabolized through catechol-O-methyl transferase (COMT).

MAOIs can be divided into reversible agents (moclobemide) or irreversible (selegiline, phenelzine, isocarboxazid, and tranylcypromine). They may also be selective to MAO-A (moclobemide) or MAO-B (pargyline, selegiline) [36–38]. The original MAOIs (e.g., phenelzine, isocarboxazid, and tranylcypromine) are nonselective irreversible MAO-A and MAO-B inhibitors [39]. Selegiline and tranylcypromine are metabolized to desmethylselegiline, levoamphetamine, and levomethamphetamine and will give a positive amphetamine on drugs of abuse urine screening [40]. The selective MAO-B and the reversible inhibitors of MAO-A (RIMA) are unlikely to cause hypertensive crisis. They are not currently available in the USA.
CAs are well absorbed orally in therapeutic dosing; peak serum levels occur 2 to 6 hours after ingestion. In overdose, gastrointestinal (GI) absorption may be delayed secondary to anticholinergic and antihistaminic properties of these drugs [41]. Metabolism is predominantly hepatic with a small enterohepatic circulation [42,43]. Some CAs have active metabolites. The volume of distribution is large, with distribution occurring within the first several hours after ingestion [44–46]. Elimination half-life averages 8 to 30 hours but may be prolonged in overdose [41,42]. Elimination is hepatic, with minimal renal involvement. Since some tertiary CAs are metabolized into their secondary amines toxicity may be prolonged after overdose because of synergistic effect and active metabolites (imipramine is metabolized to desipramine and amitriptyline is metabolized to nortriptyline). CAs are extensively bound to serum proteins, particularly α1-acid glycoprotein (AAG), and binding appears to be pH dependent [47–49]. MAO inhibitors are well absorbed orally. They have relatively short elimination half-lives [36–38,40] but since the irreversible agents permanently inhibit the activity of MAO, their effects can last for 4 to 6 weeks [36].

In therapeutic doses, CA agents and SSRIs may interact with other medications, increasing the effect of one or both agents. This effect may be magnified after an overdose. Drug interactions may alter metabolism, elimination, or the free fraction of the drug. Most antidepressants are metabolized through the CYP2D6 microsomal agents and are subject to induction and interference. Agents that stimulate the hepatic P450 microsomal system (phenobarbital, carbamazepine, phenytoin, and rifampin; and cigarette smoking) increase the clearance of CAs. Cimetidine is an inhibitor of 2D6 and can lead to elevated TCA levels. Paroxetine, fluoxetine, and norfluoxetine inhibit CYP2D6. The coadministration of CAs and antipsychotic agents may lead to competitive inhibition of the metabolism of both drugs. Other medications that increase the steady-state levels of CAs include chloramphenicol and disulfiram, whereas erythromycin decreases the level. Acute ethanol intoxication may decrease CA metabolism, resulting in markedly prolonged serum drug half-life [50].

MAOIs are both oxidized by CYP2D6 and 2C19 and acetylated by N-acetyltransferase. A large portion of the population are defined as “slow acetylators” which can lead to exaggerated and/or prolonged clinical effects. Irreversible MAOIs can have very long durations of action since new enzymes need to be synthesized to overcome their effects. Phenelzine and isocarboxazid are hydrazides and metabolized to hydrazines. These
hydrazine compounds inactivate pyridoxal 5’ phosphate, create a functional low pyridoxine state, and prevent formation of GABA from glutamate.
CLINICAL TOXICITY

General

Antidepressant toxicity predominately involves the CNS and/or the cardiovascular system. The pattern and severity of clinical effects, the clinical course, and treatment may vary significantly. Dependent on the ingested agent, progression of toxicity may be precipitous and lead to coma, hypotension, seizures, dysrhythmia, and death [51]. The newer agents (e.g., nefazodone, trazodone, and the SSRIs) are more likely to be sedating and less likely to exhibit cardiovascular toxicity [9, 52–54]. Maprotiline, venlafaxine, amoxapine, and loxapine tend to cause CNS toxicity before cardiovascular toxicity [8, 55–60]. Bupropion may cause seizures in therapeutic dosing and exhibits a dose-dependent increase in toxicity (greater than 450 mg per 24 hours) [55, 61–63]. With the CAs, if marked myoclonus or seizures develop, severe hyperthermia may result [20, 51, 64–66].

TCA toxicity

Overview

Toxicity from CAs results in CNS depression, seizures, hypotension, dysrhythms, and cardiac conduction abnormalities because of its interactions with a number of different receptors and ion channels [6, 47–49, 67]. Hyperthermia may occur as a result of increased muscle activity, seizures, and autonomic dysfunction [64, 66]. The onset of symptoms from CA overdose is rapid. Historically, most patients who die from overdose do so before arriving at the hospital and after having ingested large (greater than 1 g) amounts of a drug [51]. Signs and symptoms usually occur within the first 6 hours after ingestion. Patients who survive the first 24 hours without hypoxic insult generally do well [51]. The progression of toxicity is rapid and unpredictable with patients capable of deteriorating from an awake, alert state to seizures, hypotension, and dysrhythmias within 30 to 60 minutes and with minimal warning signs [13, 51, 53, 54]. Cardiac arrest due to CA poisoning may sometimes respond to prolonged resuscitative efforts. One case reports a patient who survived after a resuscitation of approximately 70 minutes [68].

CNS Manifestations
The CNS effects in CA overdose can be quite profound. Although some of the newer CAs are less toxic in overdose, they can cause seizures and alteration in mental status. The etiology of coma, seizures, and myoclonus is multifactorial and involves \( \text{GABA}_A \)- and \( \text{GABA}_B \)-chloride ion channel, muscarinic receptor blockade, serotonin agonism, and direct sodium channel effects \([2,5,6,17,23,24,26,31,42,45,69,70]\). Seizures typically occur early in poisoning and are generalized. Status epilepticus is uncommon. Doxepin is particularly sedating, likely because of its strong histamine antagonism. Antimuscarinic delirium—characterized by mumbling and incoherent speech; inattention; hallucinations; akesthesia; and a characteristic picking behavior—may predominate in some individuals. Other antimuscarinic effects may cause mydriasis, urinary retention, ileus, and cutaneous vasodilation (see Table 104.2). Absence of these signs does not rule out CA ingestion; however, it is unusual for patients to have significant cardiovascular disturbances without an altered mental status. Although rare, tardive dyskinesia, neuroleptic malignant syndrome, and the syndrome of inappropriate antidiuretic hormone secretion have all been reported in association with CA overdose \([9,71–73]\).

**Cardiovascular Manifestations**

Signs of cardiovascular toxicity may exist even with therapeutic dosing of classic CAs. A prolonged QTc interval and sinus tachycardia may be observed on the electrocardiogram (ECG) in nonoverdose states \([74]\). Even in therapeutic dosing, the frontal plane axis may shift rightward; the terminal 40 ms of the frontal plane QRS complex may shift to a rightward vector of 130 to 270 degrees. If computerized vector analysis is not available, a widened slurred S wave in leads I and aVL and an R wave in aVR represent this vector. As cardiovascular toxicity progresses, the ECG changes also progress. This would include a gradual progression to repolarization abnormalities, intraventricular conduction delays, ventricular dysrhythmia, high-grade atrioventricular blocks, profound bradycardias, and asystole \([54,75–79]\). Looking for these changes in overdosed or comatose patients may help in establishing a diagnosis. However, a small portion of the population normally has this unusual vector at baseline and some patients with extreme leftward axis deviation as a baseline may not show the rightward change with CA toxicity \([22,54,79]\). The absence of this finding does not rule out a classic CA poisoning; its presence with coma, seizures, dysrhythmias, or hypotension is very suggestive of CA toxicity \([54]\).
Dysrhythmias and conduction abnormalities often provide a clue to the recognition of CA overdose. These drugs significantly affect action potential propagation (particularly in ventricular myocardial cells) and the conduction system in general [80]. CAs blunt phase 0 of the action potential depolarization by blocking the fast inward flux of sodium through the sodium channel [43]. This in turn, slows the rate of rise of phase 0 (\(V_{\text{max}}\)) and slows depolarization. As ventricular conduction slows, the QRS complex widens and there the QTc prolongs because of contributions from the prolonged QRS. This also contributes to unidirectional blocks and reentrant dysrhythmias [81]. Because inward sodium flux is coupled to the calcium excitation in myocardial cells, the myocardial cells are unable to contract fully and lose inotropy [82]. Because CAs have their tightest myocardial binding during diastole, toxicity appears to be directly related to heart rate. This was elegantly demonstrated in amitriptyline-poisoned dogs where increasing heart rate caused a decrease in \(V_{\text{max}}\) and widened the QRS complex [43,83,84]. Interventions that slowed the heart rate, such as β-blockers, improved conduction but led to irreversible hypotension [85,86]. Brugada Type I patterns are possible but rare [87].

A secondary effect is seen on phase 4 of the action potential (spontaneous diastolic depolarization), leading to decreased automaticity [82,88]. Delayed repolarization occurs and may contribute to QTc interval prolongation, which has been associated with torsade de pointes [89]. Trazodone, citalopram, and escitalopram may cause marked QTc interval prolongation without QRS effect and may permit torsade de pointes (polymorphous) ventricular tachycardia in the absence of other ECG abnormalities [52,90,91].

Patients who ingest large amounts of CAs frequently present with hypotension. Several mechanisms have been suggested, including direct negative inotropic effects and dysrhythmias [92,93], with subsequent decreases in filling time and cardiac output [64,75,94,95]. α-adrenergic receptor blockade produces vasodilation and autonomic dysfunction. In addition, blockade of the biogenic amine pump prevents adequate uptake and release of these neurotransmitters as active substances, thereby contributing to hypotension [13,20,67,75,95,96]. Tachycardia is common and is because of muscarinic antagonism and reflex tachycardia from vasodilation and antihistaminic effects.

**SSRI Toxicity**

In contrast to cyclic and atypical antidepressants, SSRIs have little other receptor classes and thus toxicity occurs mainly through serotonergic effects. The pathophysiology of serotonin toxicity or serotonin syndrome is not fully understood but is believed to result from excessive 5-HT_{1A}
stimulation, although dopamine and other neurotransmitters may be involved [97]. The Serotonin syndrome is associated with SSRI use, either alone, or in combination with other agents (e.g., serotonin precursor or agonists, lithium, tricyclic antidepressants, 5-HT analogs, other SSRIs, meperidine, pentazocine, tramadol, cocaine, 3,4-methylenedioxymethamphetamine [Ecstasy], MAOIs, and herbal remedies such as Saint John’s wort) or with change in dose (increasing or decreasing), and in overdose.

Serotonin toxicity classically manifests as a clinical triad of altered mental status, autonomic dysfunction, and neuromuscular abnormalities. Toxicity exists on a spectrum from mild to life-threatening and mild toxicity may be misidentified as “side effects.” Diagnostic criteria have been proposed to aid clinicians considering the diagnosis and severe toxicity is much easier to recognize than mild or moderate toxicity. Additionally, most criteria proposed from presumed serotonin syndrome require that other disease processes first be excluded. Mental status changes range from mood abnormalities to coma. Autonomic signs and symptoms include tachycardia, hypertension, hypotension, diaphoresis, diarrhea, hyperthermia, and tachypnea. Neurologic signs include shivering, tremor, akinesia, mydriasis, myoclonus, hyperreflexia, and greater rigidity in lower extremity compared to upper extremity. Lactic acidosis, rhabdomyolysis, myoglobinuria, and multiorgan failure may develop in severe cases [97–99]. No gold standard laboratory measurement is currently available.

SSRIs, except for citalopram and escitalopram [91,99], are expected to have minimal cardiac effects. Citalopram, escitalopram, and ritanserin may significantly affect the QTc. QT prolongation via Ikr inhibition may not be seen for up to 24 hours post-ingestion. However polymorphic ventricular dysrhythmias are uncommon but cases of arrhythmia are reported from citalopram [100,101]. Overdoses with extremely large amounts of fluoxetine and citalopram have caused atrial fibrillation and bradycardias. Evidence of Na⁺ and Ca²⁺ channel blockade has been shown at extremely high serum levels [102]. Animal experiments with paroxetine required much larger doses, compared to amitriptyline, to induce dysrhythmias [103–105].

Other adverse effects of SSRIs include sexual dysfunction, platelet dysfunction, movement disorders, SIADH, and decreased bone density.

**SNRI and Bupropion Toxicity**

Seizures and cardiovascular effects are extremely common with bupropion and venlafaxine. These patients almost always have abnormalities of vital signs, reflecting a hyperadrenergic state [55]. Large ingestions of bupropion can prolong the QRS. Sodium channel blockade
likely occurs via a different mechanism than CAs, and a recent review concluded that sodium bicarbonate is unlikely to be effective in treating QRS widening from bupropion [106]. Status epilepticus and refractory shock have been reported [61–63,107–109]. Delirium can resemble severe antimuscarinic delirium with severe agitation, akisthesia, incoordination, and hallucinations. Bupropion most commonly exists as extended-release formulations and symptoms can be prolonged. In addition to causing seizures and cardiovascular toxicity, venlafaxine may cause direct muscle toxicity leading to severe rhabdomyolysis [110].

MAOI Toxicity

There are two forms of toxicity caused by MAOI: acute overdose and drug and food interactions. Toxicity from acute MAOI overdose results from the exaggerated pharmacologic effects of MAOI and may be associated with secondary complications [111]. Classic severe MAOI toxicity is biphasic with an initial excitatory and hyperadrenergic syndrome followed by profound CNS depression as monoamine neurotransmitters become depleted. Patients with acute MAOI overdoses may be asymptomatic upon presentation. Signs and symptoms typically develop within 6 to 12 hours of ingestion if the person is on the medication chronically but may be delayed for 24 hours if this is a new medication for the patient. The hallmark of MAOI overdose is rapidly fluctuating autonomic dysfunction.

The primary drug–drug interaction occurs when MAOI is taken with an indirectly acting sympathomimetic agent (e.g., ephedrine, phenylephrine, phenylpropanolamine, or amphetamine), which causes an NE surge in the peripheral sympathetic nerve terminals. MAOI and food interaction primarily involve the small amounts of tyramine or tryptophan that are normally present in certain foods (e.g., aged cheeses; smoked or pickled meats; yeast and meat extracts; red wines; Italian broad beans; pasteurized light and pale beers; and ripe avocados) and are often termed the cheese reaction. These indirectly acting agents are usually metabolized by MAO-A in the gut. When MAO-A is inhibited, tyramine absorption is unregulated, enters into the portal circulation, and causes release of stored catecholamines with resultant hypertensive response [33,34]. The onset of MAOI and food or drug interaction usually occurs within 30 to 60 minutes of ingesting the offending substance. Signs and symptoms of both food and drug interaction-induced reaction include hypertension; tachycardia or reflex bradycardia; severe (occipital) headache; nausea and vomiting; hyperthermia; altered mental status;
seizures; intracranial hemorrhage; and death.

CNS Manifestations

Early CNS manifestations are generally excitatory and are a result of increased synaptic biogenic amines possibly with increased glutamatergic transmission and decreased GABA effect. Effects include seizures, headache, stroke, agitation, akathisia, shivering, tremor, ocular clonus, hallucinations, nystagmus (ping-pong nystagmus) [112], myoclonus, posturing, hypertonia, hyperreflexia, and muscular rigidity. Coma is a late finding.

Cardiovascular Manifestations

Early cardiovascular manifestations include hypertension, tachycardia, dysrhythmias, myonecrosis, and myocarditis. Cardiovascular collapse can ensue with hypotension, bradycardia, and sudden death. ECG changes may be evident and reflect ischemic changes due to supply and demand mismatch.

If the patient survives this progression, there may be secondary complications from rhabdomyolysis, electrolyte abnormalities, lactic acidosis, and multiple organ system failure. Toxicity may last for up to 72 hours [113]. MAOI poisoning can be very challenging to manage as the patient’s vital signs can swing from a hyperadrenergic state to cardiovascular collapse resulting from rapidly and unexpectedly depleted catecholamines [114]. Hyperthermia is multifactorial and can lead to further autonomic dysregulation including acidosis and disseminated intravascular coagulation. Other effects include nausea, vomiting, diarrhea, diaphoresis, and flushing. In cases of MAOI overdose or in conjunction with serotonergic agents, marked muscle rigidity can be seen with opisthotonus and secondary hyperthermia, lactic acidemia and rhabdomyolysis.
DIAGNOSTIC EVALUATION

Patients with suspected antidepressant overdose should have routine blood analyses. Stress leukocytosis may occur with any antidepressant overdoses, especially if seizures have occurred. Electrolyte, blood urea nitrogen, creatinine, and glucose levels should be determined, with special attention to the anion gap. Because rhabdomyolysis may occur, most frequently with seizures, creatinine kinase should be followed. Urinalysis is also useful in the diagnosis of rhabdomyolysis and possible myoglobinuric renal failure. Frequent ECGs are a necessity and should be done any time the patient has a change in clinical status. Arterial blood gas and chest radiograph should be obtained as clinically indicated. Since serial measurement of serum pH may be required to gauge toxicity and arterial sampling may be extremely painful and is sometimes associated to complications such as infection, injury, and thrombosis, venous or capillary blood can be used and trended. Venous pH has been shown to strongly correlate that of an arterial sample in CA overdose [115].

Quantitative tricyclic antidepressant levels rarely, if ever, contribute to the clinical patient management. Although total tricyclic levels of more than 1,000 ng per mL have been associated with significant toxicity [41,46,53,54,76,77], there is poor correlation between toxicity and serum level. Repeated levels during resolution of toxicity may be misleading; physical signs of toxicity abate before a significant drop in serum levels because of the prolonged elimination half-life and extensive protein binding [46]. A qualitative screen using a tricyclic antidepressant immunoassay is usually sufficient. However, other drugs that have structural similarity can produce a false positive result (Table 104.5) [116], and if clinical findings are inconsistent with immunoassay results, it may be necessary to perform a more specific test such as gas chromatography with mass spectrometry. Although toxicology testing is discretionary, acetaminophen and salicylate levels and a pregnancy test in a woman of childbearing age should always be checked.

Although the differential diagnosis includes many substances that share some of the effects of CAs, duplicating the entire constellation of signs and symptoms is relatively unusual. Like CAs, anticholinergic and antihistaminic medications can cause dilated pupils, GI hypomotility, confusion, and seizures. Phenothiazines also cause these effects and may increase the QTc. Thioridazine and mesoridazine, two phenothiazines, prolong the QRS and QTc. The atypical neuroleptics (risperidone and olanzapine) have similar sedative, cardiac, and movement effects. Other drugs that affect QRS width include type IA antiarrhythmics (quinidine, procainamide, and disopyramide) and type IC antiarrhythmics (flecaïnide, encaïnide, and propafenone). Hyperkalemia and hypocalcemia also widen the QRS complex, and the latter can cause muscle twitching and myoclonus. β-blockers, particularly propranolol, cause seizures and conduction abnormalities in overdose. Tramadol, an opiate analgesic that also causes biogenic amine reuptake inhibition, may cause opioid and serotonergic toxicity, especially when given in conjunction with an SSRI or MAOI as well as seizures. Cyclobenzaprine, a muscle relaxant, and carbamazepine share the CA structure, and can cause a similar picture with sedation, hypotension, and prolonged QTc interval.
Patients who ingest antidepressants require immediate evaluation and stabilization. Those who are awake and alert should receive an oral dose of activated charcoal if conditions are appropriate. Patients who have ingested a classic TCA (amitriptyline, nortriptyline, imipramine, desipramine, clomipramine, doxepin, dothiepin, protriptyline, and maprotiline) can be safely observed in the emergency department if they are asymptomatic. An asymptomatic patient implies one with a normal ECG throughout the observation period, a mild sinus tachycardia that resolves within the first 1 to 2 hours, clear mental status, and a nontoxic acetaminophen level. This observation period is defined as a 6-hour interval during which the patient is on continuous ECG monitoring and has intravenous access in place [51,67,77,117,118]. In addition, these patients should have adequate GI decontamination and, preferably, have passed a charcoal stool. Patients should always be referred for psychiatric evaluation, and pregnant women should be directed to prenatal counseling.

No consensus has been reached on emergency department observation for patients with ingestions of immediate-release trazodone, nefazodone, venlafaxine, and the SSRIs because of the paucity of overdose data for these medications, but guidelines exist [68,119]. Observation of asymptomatic patients for 6 to 8 hours or until the ECG returns to normal or baseline is reasonable. Any patient with signs or symptoms of toxicity should be admitted to the intensive care unit (ICU). Admission (or prolonged observation) is also prudent for patients with sustained-release bupropion overdose, as seizures have been reported as far as 12 to 16 hours after ingestion. Intentional MAOI ingestions should be admitted to an ICU or monitored setting since onset of toxicity may be significantly delayed.

All symptomatic patients should have a rapid evaluation of the airway and, if obtunded or hypoventilating, be immediately intubated. Because CA toxicity increases with acidemia, an ABG demonstrating a pH less than 7.4 or hypercarbia should prompt intubation and hyperventilation even in the patient who is able to protect his or her airway. Once an airway is established, the patient should be appropriately ventilated to prevent respiratory acidosis and subsequent deterioration of his or her condition.

GI decontamination for severely ill patients presenting within an hour of ingestion, should consist of oral activated charcoal. Because some CAs have a small enterohepatic circulation, an additional one to two doses of aqueous charcoal (25 g) may be considered [120–122] if clinical
conditions are appropriate. This dose should not be administered in the presence of an ileus, gastric distention, or altered mental status with an unsecured airway. Because the majority of these agents are extensively protein bound, hemodialysis and hemoperfusion are not effective in reducing the toxic effects of CAs.

Single or brief flurries of seizures should be treated with a benzodiazepine [23,25]. Seizures are frequently isolated, and the additional use of an anticonvulsant is not indicated in this situation. Status epilepticus should be aggressively managed to prevent the development of acidosis, hyperthermia, and rhabdomyolysis [62,63,66,123–126]. As cardiotoxicity worsens dramatically in the presence of acidemia, rapid control of seizures is mandatory. Status epilepticus should be managed with large doses of benzodiazepines. In the setting of hydrazine-derived MAOI overdose and refractory seizures, empiric pyridoxine should be administered (1 to 5 gm IV). If seizures persist despite appropriate benzodiazepine dosing, propofol may be useful since it has both GABA and N-methyl-D-aspartate activity, but there are no data on its use in this setting. Barbiturates should also be considered since they directly open chloride channels. Failing this, management becomes controversial. Administering a nondepolarizing short-acting neuromuscular blocking agent such as vecuronium along with a barbiturate anticonvulsant (e.g., phenobarbital, 15 to 20 mg per kg, or thiopental, 3 to 5 mg per kg) is one option but continuous electroencephalographic monitoring should be used. Chemical paralysis helps treat or prevent hyperthermia, rhabdomyolysis, acidosis, and further deterioration. If the patient continues to have seizure activity once the paralytic has worn off, an additional dose of vecuronium should be given and more aggressive anticonvulsant or general anesthesia should be administered [25,42,127–130]. Serum alkalinization does not affect seizure activity. There is no data to suggest that other anticonvulsants such as phenytoin, levetiracetam, and valproate are effective in terminating seizures; animal data is suggestive of worsening outcomes with phenytoin.

Hypotension often responds to fluid resuscitation. Because concomitant acidosis or abnormal cardiac conduction is often present, a sodium bicarbonate solution can be used for both fluid resuscitation and serum alkalinization. A solution of 1,000 mL dextrose 5% in water with 150 mEq NaHCO₃ (roughly equivalent to 0.9% NaCl) is suggested. The rate of fluid administration should be adjusted to maintain a serum pH of 7.45 to 7.55 without causing hypernatremia. In an adult, an initial rate of approximately 200 to 300 mL per hour (1.5 to 2.0 times maintenance fluids) is usually adequate. Many clinicians give boluses of sodium bicarbonate (44 to 50 mEq per bolus) to achieve the same effect. It is difficult to adequately alkalinize the serum in the face of hypokalemia.
Since IV bicarbonate will force potassium into the cells, larger potassium doses than anticipated, will be needed to keep the patient normokalemic.

In the event of refractory hypotension, cardiovascular monitoring (arterial line, central venous pressure, systemic vascular resistance, and cardiac index by invasive or noninvasive modalities) may be necessary. Pressor therapy with direct-acting sympathomimetics, such as NE, phenylephrine, or epinephrine, has been shown to be more effective than indirect-acting agents, such as dopamine [131–133]. In experimental rat models, the combination of epinephrine and sodium bicarbonate increased survival and decreased the frequency of arrhythmias. Moreover, this duo drug regimen was found to be more efficacious than the combination of sodium bicarbonate and norepinephrine [132]. If hypotension remains refractory, an inotropic agent such as dobutamine may be required and can be directed by the cardiovascular parameters. Failing optimum medical therapy, mechanical options including intra-aortic balloon pumps and extracorporeal circulatory support is recommended.

Abnormal conduction (QRS complex greater than 120 ms in the limb leads) and ventricular dysrhythmias are treated with alkalinization. A combination of sodium bicarbonate infusion and hyperventilation may be more useful than either alone, although hyperventilation is effective if the patient cannot tolerate the sodium load [83,84,86,134–137]. By combining the two modalities, the arterial partial pressure of carbon dioxide can be maintained at approximately 30 to 35 mm Hg, which prevents cerebral vasoconstriction, while serum sodium is kept within reasonable limits. Optimal arterial pH is between 7.45 and 7.55. Ventricular dysrhythmias that are not responsive to alkalinization may respond to lidocaine. Other than β-adrenergic blockers, no antidysrhythmics have been studied; although phenytoin has been used anecdotally in the 1970s and 1980s. In animal studies, propranolol was effective in improving conduction but led to intractable hypotension [5,83,85,86,134]. Other type IA and IC antidysrhythmics are contraindicated because they worsen cardiotoxicity. Amiodarone, a class III antidysrhythmic, was found to be of no benefit in tricyclic antidepressant-poisoned animal models. In addition, it was felt that the use of amiodarone might have been detrimental because it can further prolong the QTc interval and cause negative inotropy [138]. The successful use of magnesium sulfate was reported in a 23-month-old child who presented with ventricular tachycardia after ingesting unknown amounts of amitriptyline. The child had received normal saline,
lidocaine, bicarbonate infusion, and cardioversion without effect. Subsequent magnesium sulfate resulted in normalization of the cardiac rhythm and clinical improvement [68]. Overdrive pacing is another option, but controlled studies are lacking [89].

More recently, the use of lipid emulsion therapy in the clinical scenario of lipid-soluble drug toxicity such as local anesthetics and calcium channel blockers has been gaining wide acceptance in the practice of critical care and emergency medicine [139–142]. Numerous studies have demonstrated significant cardiovascular improvement with severe lipid-soluble drug toxicity when infused with lipid emulsions. Most CAs are lipid soluble and produce significant cardiovascular instability with collapse that may be refractory to standard measures and sodium bicarbonate therapy. In animal models, infusion with lipid emulsion therapy proved to be more potent in reversing cardiac arrest and hypotension and also preventing further cardiovascular collapse [139]. Currently, there are two theories that explain why lipid emulsions may be effective. The first theory is based on the fact that the lipid emulsions create a lipid basin that sequesters lipid soluble drugs away from their site of action. The second theory is that lipid emulsions provide relief to a stressed myocardium by providing high energy to the heart [139,141]. This concept is similar to the use of high-dose insulin regimen for calcium channel blockers toxicity. In conclusion, lipid emulsion infusion should be strongly considered when conventional treatments such as oxygen therapy, fluids, inopressors, and sodium bicarbonate have failed to provide significant results.

Treatment of serotonin syndrome is primarily supportive. Sedation, paralysis, intubation and ventilation, anticonvulsants, antihypertensives, and aggressive rapid cooling may all be necessary. Some success has been achieved with the nonspecific serotonin antagonist cyproheptadine (4 to 12 mg every 8 hours orally or 4 mg per hour to a maximum of 24 mg in 24 hours) [98], but cyproheptadine has significant antimuscarinic effects. Dopamine-2-receptor antagonists, such as haloperidol, have occasionally been effective, but safety and efficacy data are lacking. Bromocriptine increases brain serotonin levels and is contraindicated, and dantrolene may enhance brain 5-HT metabolism and should not be used.

Any patient with an acute MAOI overdose or persistent signs and symptoms from food or drug interactions should be admitted to an intensive care setting for at least 24 hours. Therapy for food or drug interactions is aimed at lowering the blood pressure. A rapidly direct-acting agent that is easy to titrate is recommended (e.g., nitroprusside or nitroglycerine) [143].

Treatment of MAOI overdose is entirely supportive. Muscular hyperactivity and seizures are treated with high-dose benzodiazepines. Hyperthermia that does not respond to benzodiazepine therapy and
cooling requires rapid-sequence intubation and paralysis with a nondepolarizing agent to completely shut down muscle activity. Bromocriptine should not be used, as it has drug interactions and is an uncontrolled D<sub>2</sub> agonist and stimulant. Dantrolene is ineffective as it works peripherally and does not affect the central causes of hyperthermia [111,144]. Symptomatic or severe cardiovascular (sympathetic) hyperactivity should be treated with agents that have readily reversible effects and can be titrated to response. Agents such as nitroprusside, nitroglycerine, and esmolol are recommended. Nicardipine can also be used. For cardiovascular depression, direct-acting agents, such as epinephrine, NE, and isoproterenol, are preferred. Although MAO inhibition may prolong their effects, these agents are predominantly metabolized by catechol-O-methyltransferase.

With the exception of MAOI overdose, patients who survive the first 24 hours without major complications (hypoxia, prolonged seizures, profound acidosis, and hyperthermia) generally do well. Most patients show some improvement within 24 hours. Once cardiac conduction improves (narrowing of QRS complex to 110 ms) alkalinization can be discontinued (usually within 12 hours) and the pH allowed to normalize. If the QRS complex again widens, alkalinization should be resumed and the weaning process repeated. Once the ECG has normalized without alkalinization, the patient should be monitored for an additional 12 to 24 hours in the ICU. The patient should be awake and alert, and have passed a charcoal stool before transfer out of the unit. All overdose patients should be referred for psychiatric evaluation before discharge.

Other Management Considerations

Controversial or investigational therapies for CA poisoning include phenytoin, physostigmine, prophylactic alkalinization, mechanical cardiovascular support, antibody therapy, and adenosine antagonists [145–147]. Although phenytoin binds to voltage-dependent Na<sup>+</sup> channels and prevents propagation of seizures, it has no GABA effect and does not prevent toxic seizures [148]. Some animal studies suggested that phenytoin was effective but others did not [129,148]. Studies using phenytoin to improve cardiac conduction were poorly controlled and not reproducible [117,129,149]. Canine data showed that phenytoin transiently facilitates conduction but then increases the incidence and duration of ventricular tachycardia and does not improve survival, suggesting that phenytoin is potentially detrimental [150].

Physostigmine (see Chapter 102) has been used to antagonize the antimuscarinic effects of CAs such as agitated delirium [151,152]. However, bradycardia and asystole have been reported with physostigmine in the presence of aberrant conduction, and as a
carbamate pesticide, it may precipitate seizures [152]. Thus, physostigmine is not advocated to treat acute CA overdose and is contraindicated in those with cardiac conduction disturbances.

No studies have been done regarding prophylactic alkalinization in patients with normal cardiac condition. Because altering the pH alters the reliability of the QRS width as a predictor of cardiotoxicity, such therapy is not recommended. Alkalinization is also not without risks, including hyperosmolality, cerebral vasoconstriction, hypokalemia, and alterations in ionized calcium concentrations. There is no evidence that it affects the seizure threshold.

In moribund patients in whom conventional therapy has failed, the use of mechanical circulatory support, such as intra-aortic balloon pump assist or partial cardiac bypass, may be life-saving. In this situation, the use of extracorporeal measures supports myocardial, hepatic, and cerebral perfusion while allowing the liver endogenously to detoxify the CA [107,153–155].

Antipsychotic agents, sometimes termed neuroleptics and major tranquilizers, are primarily used to treat schizophrenia, the manic phase of bipolar disorder, and agitated behaviors. They are also used as preanesthetics and to treat drug-associated delirium and hallucinations, nausea, vomiting, headaches, hiccups, pruritus, Tourette syndrome, and a variety of extrapyramidal movement disorders (e.g., chorea, dystonias, hemiballismus, spasms, tics, and torticollis). Antipsychotics are a structurally diverse group of heterocyclic compounds; more than 50 different drugs are available for clinical use worldwide with numerous others in various stages of development. Classes include benzamide, benzepine, butyrophenone (phenylbutylpiperidine), dibenzo-oxepino pyrrole, diphenylbutylpiperidine, indole, phenothiazine, quinolinone, rauwolfia alkaloid, and thioxanthene derivatives (Table 105.1). The phenothiazine and thioxanthene classes are further subdivided into three groups (aliphatic, piperazine, and piperidine) based on central ring side-chain substitution.

Although traditionally classified by structure, antipsychotics are more ideally classified by pharmacologic profile. Each agent has a unique receptor-binding profile (Table 105.2), and this profile can be used to predict adverse effects in both therapeutic and overdose situations [1,2]. Clinical toxicity is the result of exaggerated pharmacologic activity. Antipsychotics are also classified as typical or atypical (Tables 105.1 and 105.2). Traditional or conventional antipsychotics, which readily produce extrapyramidal signs and symptoms (EPS) at antipsychotic doses, are considered typical. Newer agents that have minimal extrapyramidal side effects at clinically effective antipsychotic doses are effective for treating the negative symptoms (e.g., alogia, avolition, social withdrawal, and flattened affect) of schizophrenia and have a low propensity to cause tardive dyskinesia with long-term treatment are considered atypical [1,2]. The characterization of antipsychotics as typical or atypical is ultimately determined by receptor binding. One or more of several different receptor-binding characteristics are associated with drug atypia, and each agent is atypical for different reasons [3]. Understanding how specific receptor-binding characteristics produce clinical effects has facilitated the development of antipsychotics that separate antipsychotic activity from other activities; thus, minimizing adverse effects and maximizing patients’ compliance.

</table>

Relative neuroreceptor affinity (neuroreceptor affinity at receptor X/dopamine [D₂]-receptor affinity) indicates relative receptor antagonism at therapeutic (D₂-blocking) antipsychotic doses.

0, minimal to none; 1+, low; 2+, moderate; 3+, high; 4+, very high; EPS, extrapyramidal side effects.

aA higher M₁ and 5-HT₂ relative neuroreceptor affinity confers a lower EPS risk.

bDose-dependent incidence of extra EPS.

Adapted from references [1–20].
Antipsychotic toxicity may occur as an idiosyncratic reaction during therapeutic use or following accidental or intentional overdose. Central nervous system (CNS) and cardiovascular disturbances are the most common dose-related toxic manifestations, but other effects include the anticholinergic syndrome (see Chapter 102 and various extrapyramidal syndromes). Therapeutic use has been associated with agranulocytosis, aplastic anemia, diabetes mellitus, hepatotoxicity, hypertriglyceridemia, fatal myocardial infarction, myocarditis, neuroleptic malignant syndrome (NMS) (see Chapter 185), pancreatitis, seizures, sleep apnea, sudden infant death syndrome, sudden adult death, venous thromboembolism, and vasculitis [5–8]. Most deaths are the consequence of suicidal overdose by psychotic or depressed adults and frequently involve mixed ingestions or ingestion of the agents chlorpromazine, loxapine, mesoridazine, quetiapine, or thioridazine [10,11]. Because of a large toxic to therapeutic ratio for most antipsychotics, fatalities rarely occur. From one study, the most toxic antipsychotics result in death from poisoning for every 100 patient-years of use [10]. Dose-related effects are most pronounced in nonhabituated patients at the extremes of age.

Data have demonstrated that users of antipsychotic drugs have higher rates of sudden cardiac death than do nonusers and former users of antipsychotic drugs. For both classes of drugs, the risk of sudden cardiac death increases significantly with an increasing dose. Users of clozapine and thioridazine are associated with the greatest risk of sudden cardiac death.

PHARMACOLOGY

Antipsychotics bind to and antagonize presynaptic (autoreceptors) and postsynaptic type 2 dopamine (\(D_2\)) receptors in the CNS and peripheral nervous system. Initially, dopaminergic neurons increase the synthesis and release of dopamine in response to autoreceptor antagonism. With repeated dosing, however, depolarization inactivation of the neuron occurs, and decreased synthesis and release of dopamine occur despite ongoing postsynaptic receptor blockade.

All antipsychotics produce their therapeutic antipsychotic effect from
mesolimbic $D_2$-receptor antagonism. $D_2$-receptor affinity (potency) in this region strongly correlates with the daily therapeutic dose (see Table 105.1) [1]. Simultaneous antagonism of other $D_2$ receptors produces additional clinical effects, the majority of which are undesirable. Mesocortical receptor blockade appears to create cognitive impairment and further worsens the negative symptoms of schizophrenia. Excessive $D_2$-receptor blockade in mesocortical and mesolimbic areas, as occurs after neuroleptic overdose, may partly mediate CNS depression from these agents. Antagonism of nigrostriatal $D_2$ receptors produces EPS (e.g., acute dystonia, akathisia, and parkinsonism). $D_2$-receptor potency in nigrostriatal relative to mesolimbic areas correlates with the likelihood of developing EPS [1]. Typical antipsychotics antagonize basal ganglia $D_2$ receptors in the same dose range necessary for limbic $D_2$-receptor blockade, thus creating high EPS liability. The high-potency or typical agents (i.e., fluphenazine, haloperidol, perphenazine, thiothixene, and trifluoperazine) are most commonly associated with EPS [1]. Atypical agents have low $D_2$-receptor potency and occupancy (i.e., clozapine, olanzapine, and quetiapine) at therapeutic doses, are partial $D_2$-receptor agonists (e.g., aripiprazole), or are more site selective (i.e., sulpiride and raclopride) and preferentially antagonize limbic $D_2$ receptors [2]. Thus, they are less likely to cause EPS or worsen negative symptoms of schizophrenia at therapeutic doses.

$D_2$-receptor blockade in the anterior hypothalamus (preoptic area) may alter core temperature set point and block thermosensitive neuronal inputs and thermoregulatory responses. Hypothermia or hyperthermia may result. $D_2$-receptor blockade in the pituitary (tuberoinfundibular pathway) results in sustained elevated prolactin secretion, which may cause galactorrhea, gynecomastia, menstrual changes, and sexual dysfunction (impotence in men) [1]. The antiemetic activity of antipsychotics results from similar inhibition of dopaminergic receptors in the chemoreceptor trigger zone (area postrema) of the medulla oblongata. Antagonism of dopamine receptors presents on peripheral sympathetic nerve terminals and vascular smooth muscle cells may produce autonomic dysfunction (i.e., tachycardia, hypertension, diaphoresis, and pallor) [12]. Simultaneous blockade of $D_2$ receptors in the hypothalamus, striatum, mesocortical and mesolimbic areas, peripheral sympathetic nerve terminals, and vasculature mediates the NMS in susceptible individuals.
In addition to D₂ receptors, antipsychotics are competitive antagonists at a wide range of neuroreceptors; varied binding affinities exist at α-adrenergic (α₁,₂), dopaminergic (D₁–5), histaminergic (H₁–3), muscarinic (M₁–5), and serotonergic (5-HT₁–7) receptors (see Table 105.2) [1]. The neuroreceptor-binding profile for each agent predicts clinical effects. The ratio of other neuroreceptor-binding affinities to D₂-receptor–binding affinity (relative binding affinity) predicts the likelihood of producing those receptor-mediated effects at clinically effective antipsychotic (D₂-blocking) doses and with overdose [1]. A ratio similar to or greater than 1 makes other receptor-mediated effects likely. High relative α₁-adrenergic antagonism (i.e., aliphatic and piperidine phenothiazines, asenapine, clozapine, olanzapine, risperidone, and ziprasidone) correlates with the incidence and severity of orthostatic hypotension, reflex tachycardia, nasal congestion, and miosis. Significant relative α₂-adrenergic blockade, as occurs with asenapine, clozapine, paliperidone, and risperidone, may result in sympathomimetic effects (e.g., tachycardia). High relative H₁-receptor blockade (e.g., aliphatic and piperidine phenothiazines, asenapine, clozapine, olanzapine, and quetiapine) produces sedation, appetite stimulation, and hypotension [1]. Relative potency at M₁ receptors correlates directly with anticholinergic effects (i.e., tachycardia, hypertension, mydriasis, blurred vision, ileus, urinary retention, dry skin and mucous membranes, cutaneous flushing, sedation, memory dysfunction, hallucinations, agitation, delirium, and hyperthermia) and inversely with the incidence of extrapyramidal reactions [1]. Olanzapine, clozapine, and aliphatic and piperidine phenothiazines are associated with clinically significant anticholinergic effects. The ability of clozapine to produce sialorrhea is likely mediated by its partial agonism at M₁ and M₄ receptors [1]. High relative antagonism at 5-HT₁₆ and 5-HT₂₆ receptors appears to predict a low EPS risk [1,13]. The clinical effects that occur with other neuroreceptor subtype binding are not well understood.

The advent of atypical agents, which provide an improved motor side-effect profile, marks significant progress in the neuroleptic development. Atypical agents may be subdivided into four functional groups: (a) the D₂- and D₃-receptor antagonists (i.e., amisulpride, raclopride, remoxipride, and sulpiride); (b) the D₂-, 5HT₂₆-, and α₁-receptor antagonists (i.e., paliperidone, risperidone, and ziprasidone); (c) the broad-spectrum, multireceptor antagonists (i.e., asenapine, clozapine, olanzapine, and quetiapine); and (d) the D₂- and 5-HT₁₆-receptor partial
agonists (i.e., aripiprazole and bifeprunox), also known as dopamine and serotonin system stabilizers [2] (see Table 105.2). One or more of several different pharmacologic mechanisms define drug atypia. Low D₂-receptor potency (high-milligram dosing), low (less than 70%) D₂-receptor occupancy in mesolimbic and nigrostriatal areas at therapeutic drug doses, partial agonist activity at D₂ receptors, selective mesolimbic D₂-receptor antagonism, and high D₁-, D₄-, M₁-, 5HT₁A⁻, and 5HT₂A-receptor potencies relative to D₂-receptor-binding are pharmacologic characteristics that alone or in the combination may be responsible for the atypical nature of these agents [1,2,13]. Conversely, typical antipsychotics are characterized by high D₂-receptor potency (low-milligram dosing) and a narrow receptor profile in the brain [1]. Unlike typical agents, atypical agents also appear to have a minimal propensity to elevate serum prolactin concentrations.

Serotonin antagonism enhances antipsychotic efficacy and reduces the incidence of EPS [13]. 5HT₂A-receptor antagonism in the striatum and prefrontal cortex offsets neuroleptic-induced D₂-receptor blockade and reduces EPS and negative symptoms of schizophrenia, respectively [13,14]. 5HT₂A-receptor antagonism also increases serotonin levels in the limbic system, which may have direct antipsychotic effects. Drugs with high relative 5HT₂A-receptor antagonism as compared to D₂-receptor antagonism (i.e., amperozide, asenapine, clozapine, olanzapine, paliperidone, risperidone, and ziprasidone) can be given in smaller clinically effective antipsychotic doses, and thus, have a smaller risk of inducing EPS [1,14]. In addition, antipsychotics that stimulate 5HT₁A autoreceptors in the striatum (i.e., aripiprazole, clozapine, and ziprasidone) reduce striatal D₂-receptor blockade, thereby decreasing the likelihood of EPS [13].

Aliphatic and piperidine phenothiazines (e.g., chlorpromazine, thioridazine, and mesoridazine) have local anesthetic, quinidine-like (type IA) antiarrhythmic, and myocardial depressant effects. These agents block both fast-sodium channels responsible for myocardial membrane depolarization [15]. Sodium-channel blockade is voltage and frequency dependent; blockade is augmented at less negative membrane potentials and faster heart rates [15]. Thus, the anticholinergic properties (e.g., tachycardia) and tissue acidemia-producing effects (e.g., seizures and hypotension) of these drugs potentiate their sodium-channel blocking effects. Although specifically demonstrated for sertindole and thioridazine only, all neuroleptics appear to variably antagonize delayed-rectifier, voltage-gated, potassium channels responsible for myocardial membrane repolarization; antagonism occurs specifically at the
potassium channel encoded by the human ether-a-go-go (hERG) gene [16]. Potassium-channel blockade is concentration-, voltage-, and reverse-frequency dependent; blockade is increased at higher tissue concentrations, less negative membrane potentials, and slower heart rates [16]. Potassium-channel blockade may result in early after depolarizations and subsequent torsade de pointes (TdP)–type ventricular tachycardia. Haloperidol, mesoridazine, thioridazine, and pimozide share an added property of calcium-channel blockade [17].

Electrophysiologic effects variably include a depressed rate of phase 0 depolarization, depressed amplitude and duration of phase 2, and prolongation of phase 3 repolarization. Ventricular repolarization abnormalities, such as T-wave changes (blunting, notching, and inversion), increased U-wave amplitude, and prolongation of the QT interval, are the earliest and most consistent electrocardiographic changes produced by neuroleptics [17,18]. Dose-related prolongation of the QT interval has been described with droperidol, haloperidol, loxapine, phenothiazines, pimozide, quetiapine, risperidone, sertindole, and ziprasidone [11,16,18–23]. Conduction disturbances (i.e., bundle-branch, fascicular, intraventricular, and atrioventricular [AV] blocks) and supraventricular and ventricular tachyarrhythmias (i.e., monomorphic and polymorphic TdP ventricular tachycardia, ventricular fibrillation) have been reported [11,20,24]. Cardiac effects are dose and concentration dependent but can occur with therapeutic as well as toxic doses. Ventricular tachyarrhythmias and asphyxia (caused by seizures, aspiration, or respiratory depression) have been postulated as etiologies of sudden death for patients taking therapeutic doses of antipsychotics, particularly phenothiazines [9,25].

Antipsychotics produce dose-related electroencephalographic changes, and some agents have been shown to lower the seizure threshold [26,27]. The risk of seizures is dose related, and thus, greatest after overdose [27]. Chlorpromazine, clozapine, and loxapine are the most likely agents to produce seizures [26,27]. Most other agents, however, are uncommonly associated with seizures, even after overdose. The mechanism by which antipsychotics produce seizures is not well understood but likely involves dose-related blockade of norepinephrine reuptake, antagonism of γ-aminobutyric acid type A receptors, and altered neuronal transmembrane ionic currents.

Antipsychotics have a relatively flat dose–response curve. Effective therapeutic doses vary over a wide range (see Table 105.1). The optimal dose is determined by the clinical response, but not by serum drug levels.
Pharmacologic effects generally last 24 hours or more, allowing for once-daily dosing. Tablet, capsule, and liquid oral preparations, suppository, and injectable immediate-release and sustained-release (depot) solutions are available. Oral preparations include both rapidly disintegrating (sublingual absorption) and sustained-release formulations. Paliperidone, the active metabolite of risperidone, is commercially available in an extended-release oral preparation (Invega). Following a single dose, plasma concentrations gradually rise and do not peak until approximately 24 hours after dosing [28]. Slow-release, highly lipophilic depot formulations (i.e., fluphenazine enanthate and decanoate, haloperidol decanoate, and paliperidone palmitate) for intramuscular (IM) injection are created by esterifying the hydroxyl group of an antipsychotic with a long-chain fatty acid and dissolving it in a sesame oil vehicle.

Antipsychotic pharmacokinetics are complex and incompletely understood. When administered orally, they are well absorbed, but bioavailability is unpredictable (range 10% to 70%) owing to large interindividual variability and presystemic (hepatic and intestinal) metabolism [29,30]. After parenteral administration, drug bioavailability is 4 to 10 times greater than with oral dosing because of the absence of first-pass metabolism [29,30]. Hence, therapeutic intravenous (IV) or IM doses are substantially less than oral ones. Plasma concentrations peak for 1 to 6 hours after therapeutic oral and sublingual dosing, 30 minutes to 1 hour after immediate-release IM injection, and within 24 hours after oral dosing of extended-release preparations. After a single IM dose of a depot preparation, plasma concentrations peak variably from a few days to over 2 weeks after initial injection [28–30]. After oral overdose, absorption should occur more rapidly (first-order kinetics), but peak plasma concentrations are delayed, because more time is required for complete absorption. As a result, clinical effects are expected to occur sooner and last longer. Erratic absorption may occur after ingestion of agents with significant anticholinergic effects.

After absorption, antipsychotics are highly bound to plasma proteins (75% to 99%) [29,30]. However, because they are also highly lipophilic, volumes of distribution are large (10 to 40 L per kg), and serum drug levels after therapeutic doses are quite low (one to several hundred ng per mL). These pharmacokinetic characteristics make extracorporeal removal by hemodialysis or hemoperfusion impractical. Antipsychotics tend to accumulate in the brain, easily cross the placenta, and are found in breast milk. Elimination occurs slowly and extensively by hepatic metabolism, with serum concentration half-lives averaging 20 to 40 hours. Depot antipsychotics have an apparent elimination half-life of 1 to 3 weeks due to slow tissue absorption [29]. Small amounts (1% to 3%) are excreted unchanged by the kidney. As a rule, hepatic metabolism yields multiple
metabolites, some of which are pharmacologically active and likely to extend parent drug effects after therapeutic or toxic dosing [31,32]. Metabolites are eliminated by urinary and biliary excretion and can be detected in the urine for several days after a single ingestion and for a month or more after cessation of long-term therapy [30]. Large interindividual variations in the metabolism of neuroleptics result in significant differences of steady-state plasma concentrations with fixed, therapeutic dosing [29,30,33]. There is often little correlation among neuroleptic dose, serum concentrations, and clinical effects.

Renal insufficiency may rarely result from drug accumulation and toxicity [34]. Renal excretion accounts for a significant proportion of total drug elimination for the benzamide (e.g., remoxipride and sulpiride) and benzisoxazole derivatives (e.g., paliperidone and risperidone) [28–30]. Thus, dose alteration is recommended for patients with renal insufficiency who regularly take these agents. Other neuroleptics, however, do not routinely require dose alteration for patients with renal impairment. Dose adjustment is also recommended for those patients who have a diminished ability to clear neuroleptics, such as the elderly and those with significant hepatic disease or specific cytochrome P450 enzyme deficiencies (i.e., CYP2D6 and CYP1A2) [30]. Most antipsychotics are pregnancy category C and should be used in pregnancy only if the potential benefit justifies the potential risk to the fetus. Breast feeding is not recommended for women taking neuroleptics because most neuroleptics are secreted into breast milk, and their safety for infants is not established.

The majority of the patients who take an accidental or intentional overdose of an antipsychotic agent remain asymptomatic or develop only mild toxicity [3]. Toxic effects result from exaggerated pharmacologic activity and include CNS and consequent respiratory depression, miosis or mydriasis, cardiovascular abnormalities, agitation, confusion, delirium, anticholinergic stigmata, seizures, EPS, and myoclonic jerking. Hypothermia and, less commonly, hyperthermia have occurred. Hypothermia may result from α₁-adrenergic–mediated peripheral vasodilation at low ambient temperature, hypotension, coma, loss of shivering capabilities, and disrupted hypothalamic thermoregulation. Peripheral vasodilation at high ambient temperature, seizures, neuromuscular agitation, loss of sweating capabilities, and hypothalamic dysfunction may contribute to hyperthermia. Seizures are uncommon and occur mainly among the patients with underlying epilepsy and those with clozapine and loxapine overdoses. In one study of 299 patients with neuroleptic overdose, the incidence of seizure was only 1% [11]. Rhabdomyolysis, myoglobinuria, and acute renal failure may occur after prolonged convulsions [35]. CNS depression is the most frequent clinical finding after neuroleptic overdose [11,36,37]. Sinus tachycardia and
orthostatic hypotension are the most frequent cardiovascular findings [36–38]. Other cardiovascular effects include hypertension, cardiac conduction disturbances, tachyarrhythmias, bradyarrhythmias, and, rarely, pulmonary edema [39,40]. Anticholinergic stigmata (see Chapter 102) may occur after overdose with aliphatic and piperidine phenothiazines, clozapine, and olanzapine [3,38,41–43].

Of the thousands of antipsychotic overdoses reported each year, less than 1% result in fatal toxicity [10]. Fatality is most often due to respiratory arrest before medical intervention, arrhythmias, or aspiration-induced respiratory failure [3,9]. Toxic and lethal doses are highly variable and are influenced by the agent ingested, the presence of coingestants and comorbid illness, the age and habituation of the patients, and the time to treatment. Nonhabituated patients at the extremes of age are more sensitive to the toxic effects of these drugs than those who have taken this drug chronically before an acute overdose. The ingestion of a single tablet of chlorpromazine, clozapine, loxapine, mesoridazine, olanzapine, quetiapine, or thioridazine may cause CNS and respiratory depression of young children [3,34,35,41]. Death of an infant was reported after the ingestion of only 350 mg of chlorpromazine. In general, acute ingestion of greater than twice a maximal therapeutic dose is potentially serious.

Unintended adverse effects that occur during therapeutic use may be idiosyncratic or dose related, occur early or late during the course of therapy, or result from interactions with other drugs, and are often due to receptor antagonism. The major adverse side effect, in terms of both prevalence and distress that it causes, is the tendency to induce extrapyramidal dysfunction.

Extrapyramidal syndromes are a group of movement disorders that result from the interference with neurotransmitter (primarily D2-receptor blockade) function in the basal ganglia. EPS occur in up to 75% of the patients treated with low-milligram, high-potency traditional agents (e.g., fluphenazine, haloperidol, and thiothixene), but an incidence not significantly different from placebo (<5%) has been described with newer atypical agents (e.g., aripiprazole, olanzapine, and quetiapine) [44]. EPS may occur early (i.e., within a few hours to days), at an intermediate stage (i.e., a few days to months), or late (i.e., after >3 months) in the course of therapy. Early EPS include acute dyskinesia (acute dystonic reactions [ADRs]), intermediate syndromes include akathisia and parkinsonism, and late disorders include tardive dyskinesia, tardive dystonia, and focal perioral tremor (rabbit syndrome). EPS are more commonly associated with therapeutic doses of neuroleptics but may follow acute overdose (e.g., ADRs), particularly among children [3,36,45]. Only ADRs, the acute syndrome most likely to develop in the intensive care unit, are discussed.
ADRs are reversible motor disturbances consisting of sustained, uncoordinated, and involuntary spasmodic movements of various muscle groups. Although ADRs most often occur after administration of therapeutic doses of antipsychotics [46], they have also been described after administration of antihistamines (both H₁- and H₂-blockers), anticholinergics (e.g., benztropine and diphenhydramine), anticonvulsants (e.g., carbamazepine and phenytoin), calcium-channel blockers (e.g., nifedipine and verapamil), metoclopramide, cyclic antidepressants (e.g., amitriptyline, amoxapine, doxepin, and imipramine), selective serotonin reuptake inhibitors (e.g., fluoxetine and sertraline), monoamine oxidase inhibitors (e.g., phenelzine and tranylcypromine), anesthetic induction agents (e.g., ketamine, etomidate, and thiopental), cholinergics (e.g., bethanechol and insecticides), and cocaine. ADRs can also occur as a primary (non-drug–related) disorder [47].

The pathophysiology of ADRs is not fully elucidated but involves a disruption of cholinergic (interstriatal) and dopaminergic (nigrostriatal) pathways in the basal ganglia. Normally, dopamine is an excitatory neurotransmitter and acetylcholine is an inhibitory neurotransmitter [48]. Normal balance between these closely linked pathways is necessary for coordinated muscular activity. Dopaminergic D₁-, γ-aminobutyric acid-(striatonigral), glutaminergic-(corticostriatal), noradrenergic-, 5HT₁₅- and 5HT₂₅- (raphe- striatal and raphe-nigral), and sigma (σ)- (red nucleus, substantia nigra, and cranial nerve motor nuclei) receptor inputs modulate this balance [13,49]. Blockade of striatal D₂ receptors by high-potency neuroleptics disrupts the dopaminergic–cholinergic balance in favor of cholinergic excess and dystonia results [50,51]. Agents that balance D₂-receptor antagonism with D₁-, M₁-, or 5HT₂₅-receptor antagonism or 5HT₁₅-receptor agonism prevents striatal cholinergic excess and are less likely to precipitate acute dystonia [1,13,52]. γ-aminobutyric acid–receptor affinity correlates inversely, whereas σ- and N-methyl-D-aspartate-glutamate receptor–binding affinities correlate directly with the clinical incidence of acute dystonia [49].

Paradoxically, ADRs may also result from hyperdopaminergic function induced by D₂-receptor blockade in the basal ganglia [53,54]. Acute D₂-receptor blockade may stimulate increased dopamine synthesis and release from nigrostriatal neurons and postsynaptic receptor upregulation (supersensitivity). Because brain concentration of drug declines hours to days after a dose, a state of dopamine excess develops,
and dystonia results [53,54].

ADRs usually occur soon after initiation of therapy or after an increase in dose. Fifty percent of ADRs occur within 48 hours of initiating therapy, and 90% within 5 days [55]. Peak incidence occurs when drug levels are declining in the serum. Although the absolute incidence of ADRs is unknown, they are estimated to occur in 25% of the patients treated with IM depot preparations, 16% of the patients who have been given haloperidol, 8% of the patients treated with thiothixene, 2% to 12% of all patients who take phenothiazines, 3.5% of the patients treated with chlorpromazine, and 1% or less in patients taking atypical agents [50,55]. Phenothiazines that contain a piperazine side chain (i.e., prochlorperazine, trifluoperazine, perphenazine, fluphenazine, and acetophenazine) are associated with a higher incidence of dystonic reactions than are other phenothiazines [55]. Atypical agents (particularly clozapine) are unequivocally associated with a reduced incidence of ADRs. The likelihood of an ADR is more dependent on individual susceptibility than on neuroleptic structure, potency, dose, and duration of therapy [56]. ADRs most commonly occur among men, patients 5 to 45 years of age (particularly those younger than 15 years old), and those with a personal or family history of dystonia or a recent history of drug (i.e., cocaine) or alcohol abuse [55,57].

Seizures are an uncommon side effect of certain antipsychotics (e.g., clozapine, chlorpromazine, and loxapine). They typically occur at higher therapeutic doses and after overdose of susceptible patients. Seizures are usually generalized and of the major motor type. Clozapine, the most epileptogenic agent at therapeutic dosing, is associated with a seizure rate of approximately 1% at doses lower than 300 mg per day, a rate of 2.7% at doses between 300 and 600 mg per day, and a rate of 4.4% with doses larger than 600 mg per day. A cumulative seizure risk of 10% after 3.8 years of treatment has been demonstrated with clozapine [38,39]. Newer, atypical agents show no increase of seizure risk when compared with haloperidol or placebo. Other risk factors for seizures include a history of organic brain disease, epilepsy, electroconvulsive therapy, abnormal baseline electroencephalogram, polypharmacy, and initiation and rapid dose titration of neuroleptics [27]. After overdose, the incidence of seizures is as high as 60% and 10% for loxapine and clozapine, respectively, whereas the incidence for most other neuroleptics is approximately 1% [3,11].

Agranulocytosis (absolute neutrophil count < 500 cells per μL) is a serious idiosyncratic side effect of clozapine and phenothiazine therapy. It is rare (0.1 to 1.0 per 1,000 persons) with phenothiazines and usually occurs in the first 12 weeks of therapy [58,59]. A cumulative risk of 0.91% (9 per 1,000 persons) at 18 months is reported with clozapine; more than 80% of the cases occur in the first 3 months [5,60]. Initial mortality rates
associated with agranulocytosis ranged from 30% to 85%, but with regular white blood cell count monitoring and treatment with granulocyte colony stimulating factor (G-CSF), mortality rates have dropped to 3% to 4% [5,60,61]. The mechanism underlying clozapine-induced agranulocytosis may be both immune-mediated and the result of direct myelotoxicity from the drug. G-CSF has been useful for treatment, halving recovery time from 16 to 8 days [62]. Agranulocytosis has not been reported after acute overdose. Neutropenia has also been associated with the therapeutic use of olanzapine, quetiapine, and risperidone [63].

Hepatic transaminitis is an adverse side effect of most antipsychotics [7]. Hepatotoxicity is idiosyncratic, often occurs within the first 3 months of treatment, and is usually mild and self-limiting (most patients remain asymptomatic). The patterns of hepatotoxicity are both hepatitic (including nonalcoholic steatohepatitis) and cholestatic [63,64].

Most atypical neuroleptics result in an increased appetite and weight gain. More importantly, and perhaps causally related, the therapeutic use of atypical agents has been associated with an increased risk of developing type II diabetes mellitus [57–67]. Several cases of fatal diabetic ketoacidosis and hyperglycemic hyperosmolar nonketotic coma have been reported among the patients taking clozapine and olanzapine [68,69]. Pancreatitis has been associated with the use of clozapine, and hypertriglyceridemia has been reported among patients treated with clozapine, olanzapine, and quetiapine [56,70–72].

Allergic dermatitis, cholestatic jaundice, irreversible pigmented retinopathy, photosensitivity reactions, and priapism are uncommon idiosyncratic reactions associated with phenothiazine therapy [7]. Myocarditis and cardiomyopathy have been rarely associated with the use of clozapine; these conditions are idiosyncratic, frequently fatal, often occur within the first 2 weeks of treatment, and are likely the result of acute hypersensitivity [8,73].

Drug interactions and adverse effects may be pharmacodynamic (i.e., receptor or channel mediated) or pharmacokinetic (i.e., altered absorption, metabolism, or protein binding) [74]. Combining antipsychotics with other CNS depressants (i.e., antihistamines, cyclic antidepressants, ethanol, opiates, and sedative-hypnotics) may produce enhanced CNS and respiratory depression. Respiratory depression and arrest have been reported with the coadministration of clozapine and lorazepam or diazepam [75,76]. Exaggerated anticholinergic effects may occur with concurrent use of tricyclic antidepressants, certain skeletal muscle relaxants, antihistamines, and antiparkinson agents. The
combination of antipsychotics with significant $\alpha_1$-adrenergic blockade and certain antihypertensive agents (e.g., hydralazine and prazosin) may precipitate hypotension. Enhanced cardiotoxicity may occur when mesoridazine or thioridazine is combined with type IA antiarrhythmic agents or tricyclic antidepressants. High-dose droperidol, haloperidol, sertindole, thioridazine, and ziprasidone may potentiate QT prolongation produced by other cardioactive agents.

Most antipsychotic agents are extensively metabolized by the hepatic cytochrome P450 (CYP) enzyme system, particularly the CYP2D6 and CYP1A2 isoenzymes. Other drugs that are substrates (i.e., cyclic antidepressants), inhibitors (i.e., cimetidine, erythromycin, and selective serotonin reuptake inhibitors), or inducers (i.e., anticonvulsants) of similar CYP isoenzymes may alter antipsychotic metabolism and precipitate adverse effects. These interactions often go unnoticed, but they may be clinically significant. Cimetidine, erythromycin, and fluvoxamine have precipitated clinical clozapine toxicity from hepatic CYP1A2 isoenzyme inhibition [77,78]. Paroxetine may precipitate risperidone toxicity from CYP2D6 isoenzyme inhibition. Knowledge of antipsychotic-associated drug interactions facilitates recognition and treatment of these increasingly common iatrogenic events.
Acute overdose may result in nausea and vomiting soon after ingestion. CNS and cardiovascular effects, however, usually dominate the clinical picture \([\text{3,11,23,36,37]}\). For mild intoxication, findings include ataxia, confusion, lethargy, slurred speech, tachycardia, and hypertension or orthostatic hypotension. Anticholinergic signs (e.g., dry skin and mucosa, decreased bowel sounds, and urinary retention) and hyperreflexia may also be present. Although usually considered an idiosyncratic reaction, EPS (e.g., ADRs) have been described after acute neuroleptic overdose, particularly among children \([\text{3,36,45]}\). Electrocardiographic changes such as prolonged PR and QT intervals, ST-segment depression, T-wave abnormalities (biphasic, blunting, inversion, notching, and widening), and increased U waves can occur \([\text{11,18,19]}\). Other than sinus tachycardia, repolarization abnormalities are the earliest and most common electrocardiographic findings associated with neuroleptic poisoning \([\text{11,18,19,79]}\).

Signs and symptoms of moderate poisoning include low-grade coma (see Chapters 145 and 146, respiratory depression, and hypotension). Miosis or mydriasis may occur. Miosis is more likely to occur following overdose of both atypical and typical agents; it has been described in 75% of the adults and 72% of the children after phenothiazine overdose \([\text{3,37,38,41,80]}\). Internuclear ophthalmoplegia has been reported. Paradoxical agitation, delirium, hallucinations, psychosis, myoclonic jerking, and tachypnea may occur \([\text{3,38,41–43,81]}\). Central and peripheral anticholinergic stigmata frequently occur after overdose with chlorpromazine, clozapine, mesoridazine, olanzapine, and thioridazine \([\text{3,38,41–43]}\).

With severe poisoning, high-grade coma with loss of most or all reflexes, apnea, hypotension, seizures, and a variety of cardiac conduction disturbances and arrhythmias may develop. Conduction disturbances include all degrees of AV block, bundle-branch and fascicular block, and nonspecific intraventricular conduction delay \([\text{11,19,20,24,79]}\). Bradyarrhythmias occur uncommonly and, when present, may signify impending respiratory arrest. Tachyarrhythmias include sinus and supraventricular tachycardias, supraventricular and ventricular premature beats, ventricular tachycardia and fibrillation, and TdP \([\text{3,11,18–20,24,82]}\). The latter arrhythmia typically occurs in the setting of QT-interval prolongation and has been described with amisulpride, droperidol, haloperidol, mesoridazine, pimozide, and thioridazine \([\text{83]}\). TdP has also been described when critically ill patients are given haloperidol for sedation. In one study, TdP occurred in 3.6% of
such patients; the incidence was 64% in those given greater than 35 mg of haloperidol in less than 6 hours and 84% when given to those with a corrected QT (QTc) interval greater than 500 milliseconds [84]. TdP has been rarely associated with therapeutic (usually large) doses of droperidol [20,85]. Discovery of this association prompted the Federal Drug Administration to issue a “black box” warning to US health care personnel for droperidol in 2001 [86]. Serious cardiovascular toxicity occurs more commonly when piperidine phenothiazines have been ingested [11]. In one study of 299 patients with neuroleptic overdose, thioridazine was associated with a significantly greater incidence of prolonged QRS, prolonged QTc, and arrhythmia as compared to other neuroleptics [11]. Electrocardiographic abnormalities or obvious cardiotoxicity should be evident within several hours of overdose. Newer agents alter cardiac conduction less frequently but are not entirely void of cardiotoxicity. Prolonged QRS and QT intervals and hypotension have been described after risperidone overdose, and ventricular tachycardia has occurred after remoxipride overdose. The new drug approval application for sertindole was withdrawn in the United States due to dose-related prolongation of the QT interval that occurred during premarketing trials with the drug [22].

Although the overall seizure incidence is about 1% for patients that overdose on neuroleptics, the incidence is much greater following ingestion of chlorpromazine, clozapine, loxapine, mesoridazine, and thioridazine [3,10,11]. Occasionally, hypothermia or hyperthermia may be seen [87]. Pulmonary edema has been reported rarely as a complication of overdose with chlorpromazine, clozapine, haloperidol, and perphenazine [3,39,40]. NMS is an idiosyncratic reaction that rarely occurs after acute overdose. Acute overdose, however, may infrequently produce a clinical picture (i.e., the presence of hyperthermia, autonomic instability, neuromuscular hyperreactivity, and hypertonia) that could be misinterpreted as NMS. Agents that produce anticholinergic effects (e.g., clozapine, mesoridazine, olanzapine, and thioridazine) would be more likely to do this.

Loxapine poisoning results in an atypical clinical picture. Cardiovascular effects are mild or absent, but convulsions are common and often lead to rhabdomyolysis and subsequent renal failure [88].

Following overdose, toxic effects (e.g., CNS depression) begin within 1 to 2 hours, maximal severity is usually evident by 2 to 6 hours, and resolution usually occurs by 24 to 48 hours after ingestion. The presentation is the same regardless of age and whether the overdose is acute or chronic. Early deaths are due to respiratory arrest, arrhythmias, shock, or aspiration-associated respiratory failure. Later complications include cerebral and pulmonary edema, disseminated intravascular coagulation, rhabdomyolysis, myoglobinuric renal failure, and infection.
ADRs are characterized by abrupt onset, intermittent and repetitive nature, normal physical examination except for muscular findings, a history of recent neuroleptic use, and rapid response to anticholinergic drug therapy [50,55]. Muscle contractions may sometimes be sustained but usually last from seconds to minutes. They may be focal at the onset and then spread to contiguous muscles; occasionally, they are generalized [89]. The patients remain alert and oriented during these reactions.

Although dystonia may occur in any striated muscle, one of the five areas is typically affected [50,55,90]. ADRs involving the muscles of the eye (oculogyric crisis) cause upward gazing, rotation of the eyes, and spasm of the lids. Those involving muscles of the tongue and jaw (buccolingual crisis) produce trismus, protrusion of the tongue, dysphagia, dysarthria, and facial grimacing. Contraction of muscles of the neck or back result in abnormal head positioning (torticollie reactions) or arching and twisting of the torso (opisthotonic posturing), respectively. When muscles of the abdominal wall are involved, the patients present with abdominal wall pain and spasm, bizarre gait patterns, kyphosis, and lordosis (tortipelvic and gait crises). Buccolingual and torticollic ADRs are the most common [55].

Although ADRs are rarely life threatening, those involving the tongue, jaw, neck, and chest can result in upper airway compromise and impaired respiratory mechanics. Stridor can occur in those with buccolingual and torticollic reactions. Death from respiratory failure has been reported [91].
DIAGNOSTIC EVALUATION

The diagnosis of antipsychotic poisoning is made from a history of exposure, physical findings, and supporting evidence from electrocardiographic, laboratory, and other ancillary studies. A complete history should be obtained from the patient as well as the person(s) who found or brought the patient (to corroborate the patient’s history). As with all drug ingestions, the name, quantity, and time of ingestion of the drug(s) should be determined. For patients who become toxic during chronic therapy, a recent medication or dose change or an illness may be responsible. The patients and family members should be specifically questioned about the possibility of antipsychotic exposure when signs of an EPS are present.

Physical examination should focus on the vital signs, respiratory function, and neurologic status. Physical findings that suggest neuroleptic poisoning include CNS and respiratory depression, sinus tachycardia, miosis, anticholinergic stigmata, orthostatic hypotension, and the presence of EPS. The patients should be examined for evidence of coexisting trauma. An initial rhythm strip and subsequent 12-lead electrocardiogram (ECG) should be evaluated. Arterial blood gas determinations and a chest radiograph should be ordered for patients with significant CNS depression. An abdominal radiograph showing radiopaque densities in the gastrointestinal (GI) tract may suggest butyrophenone or phenothiazine poisoning if the etiology of symptoms is unknown. The absence of this finding, however, does not rule out poisoning by these agents. Routine laboratory evaluation should include a complete blood cell count and electrolyte count and blood urea nitrogen, creatinine, and glucose tests. Measurements of serum acetaminophen and salicylate should be performed on all patients with intentional overdose. Among the patients with seizures, hyperthermia, and severe poisoning, laboratory evaluation should include urinalysis (routine and for myoglobin); creatinine phosphokinase, calcium, magnesium, and phosphate tests; and a coagulation profile. Women of childbearing age should have a pregnancy test performed.

Toxicologic analyses of the urine and serum by immunoassay and chromatography–mass spectrometry may be performed to confirm the identity of the offending agent and to rule out other ingestants [92]. Quantitative drug levels are not helpful for predicting clinical toxicity or guiding treatment [29,30,33]. Although neither sensitive nor specific, or readily available, the Forrest, Mason, and Phenistix colorimetric tests are rapid urine screens that may be positive with phenothiazine ingestions [93]. These tests, however, do not detect nonphenothiazine neuroleptic
agents. Certain neuroleptics (e.g., chlorpromazine, mesoridazine, quetiapine, and thioridazine) will commonly produce false positive results for tricyclic antidepressants on most commercially available immunoassay screens used by hospitals to test for drugs of abuse [94].

The patients with ADRs should be questioned regarding current medications, previous ADRs, recreational drug use, and change in the dose of a neuroleptic or other medication associated with this syndrome. The diagnosis is made on the basis of history of drug exposure and the physical examination.

A complete blood cell count should be performed for patients who develop a fever or infection while taking clozapine or phenothiazines.

Agents that cause CNS and cardiovascular effects similar to those resulting from antipsychotic poisoning include antiarrhythmic, anticholinergic, anticonvulsant, antidepressant, antihistamine, opioid, other psychotropic agents (e.g., lithium, bupropion) and sedative–hypnotics, and skeletal muscle relaxants. It may be impossible to distinguish cyclic antidepressant or type IA antiarrhythmic agent poisoning from poisoning due to chlorpromazine, thioridazine, or mesoridazine without toxicologic analysis. CNS infection, cerebrovascular accident, occult head trauma, and metabolic abnormalities should also be considered in the differential diagnosis.

The differential diagnosis of an ADR includes primary dystonias, seizures, cerebrovascular accident, encephalitis, tetanus, hypocalcemia, drug intoxication (especially anticholinergic, anticonvulsant, and strychnine), hysterical conversion reactions, joint dislocations, meningitis, hypomagnesemia, torticollis, and alkalosis.
MANAGEMENT

All patients who are symptomatic after acute overdose should be observed until they are alert. Those with mild toxicity can often be managed in the emergency department or a similarly equipped observation unit. Those with protracted hypotension, significant CNS depression or agitation, seizures, acid–base disturbances, nonsinus arrhythmias, and cardiac conduction disturbances should be admitted to an intensive care unit. The patients with ECG abnormalities (e.g., prolonged QRS or QTc intervals) who are otherwise asymptomatic should be admitted to a cardiac monitored bed; such findings have been implicated in sudden death.

Treatment is primarily supportive. The tempo and sequence of interventions depend on the clinical severity. Advanced life support measures should be instituted as necessary, and underlying metabolic abnormalities corrected. All patients require cardiac and respiratory monitoring. Vital signs should be obtained frequently. Endotracheal intubation for airway protection or ventilatory support may be required. The patients with seizures or hyperthermia should have continuous (rectal probe) temperature monitoring. Those with altered mental status should receive supplemental oxygen and be given a diagnostic trial of naloxone (2 mg IV), dextrose (25 g IV), and thiamine (100 mg IV). Although reversal of CNS depression after naloxone administration has been reported [95], such a response is inconsistent with the pharmacology of neuroleptics and should not be expected.

Hypotension should be initially treated with Trendelenburg position and several liters (10 to 40 mL per kg IV) of normal saline. $\alpha_1$-Adrenergic agonists (i.e., norepinephrine and phenylephrine) are first-line agents for treating refractory hypotension, particularly in the patients who have been poisoned by antipsychotics with significant $\alpha_1$-adrenergic blockade. Central venous, intra-arterial, and echocardiographic monitoring may be necessary for optimal management of the patients who are hemodynamically unstable.

Sinus and supraventricular tachycardias rarely require specific treatment. If they are associated with hypotension, correction of this abnormality is often all that is necessary. Sodium bicarbonate (1 to 2 mEq per kg IV) may be effective and is strongly recommended for patients who
have wide QRS complexes or ventricular tachyarrhythmias. Amiodarone and electrical cardioversion are alternative treatments for patients with ventricular tachyarrhythmias, depending on hemodynamic stability. Type IA (i.e., disopyramide, quinidine, and procainamide), type IC (i.e., propafenone), and type III (i.e., amiodarone) antiarrhythmic drugs are not recommended and are potentially dangerous; they may worsen cardiac conduction abnormalities[96]. TdP ventricular tachycardia should be treated with magnesium (50 to 100 mg per kg IV over 1 hour); or an increase in heart rate (overdrive pacing) should be treated using isoproterenol or a pacemaker[97]. Increasing the heart rate may shorten a prolonged QT interval and thus facilitate conversion of this arrhythmia. The blood pressure should be carefully monitored during isoproterenol administration, as it may cause or worsen hypotension. A search for and correction of hypokalemia, hypomagnesemia, and other electrolyte disturbances is requisite to the management of TdP. Bradyarrhythmias associated with hemodynamic compromise should be treated with atropine, epinephrine, dopamine, or isoproterenol according to current advanced cardiac life support protocols. Complete heart block may require temporary cardiac pacing.

Recent literature supports the antidotal use of intravenous fat emulsions (IFE) for severe CNS or cardiovascular toxicity from highly lipophilic drugs[98]. IFE infusions may create a “lipid sink” whereby lipophilic drugs are sequestered in a newly created intravascular lipid compartment, thereby reducing tissue binding. Alternatively, IFE infusions may restore myocardial function by providing exogenous fatty acid substrate or by increasing intracellular calcium for myocyte function[98]. In clinical case reports, IFE administration has been temporally associated with attenuation of QTc prolongation and CNS depression from quetiapine overdose[99]. The overwhelming majority of the antipsychotic-overdose patients do well with good supportive care and would not necessitate IFE infusion therapy. IFE treatment, however, should be strongly considered and is recommended for patients with severe and refractory cardiovascular or CNS toxicity from antipsychotic drugs. IFE is commonly administered an IV bolus followed by a 3 to 24 hour continuous infusion. A reasonable dosing algorithm for both adults and children is a 1 to 2 mL per kg IV bolus of 20% IFE over 1 minute followed by 0.25 to 0.5 mL/kg/min continuous IV infusion (total dose 2 g/kg/d IFE)[98].

Seizures are often self-limited and may not require specific treatment. If prolonged or recurrent, seizures should be treated with incremental doses of diazepam or lorazepam (initial dose, 0.05 to 0.10 mg per kg IV). A short-acting barbiturate (e.g., amobarbital, 10 to 15 mg per kg IV at a maximal rate of 100 mg per minute) or a long-acting one (e.g., phenobarbital, 20 mg per kg IV at a maximal rate of 30 mg per minute)
may sometimes be necessary. The effectiveness of phenytoin is not established for neuroleptic-associated seizures. Refractory convulsions may require the use of a paralyzing agent to prevent complications such as hyperthermia and rhabdomyolysis. A nondepolarizing neuromuscular blocker, such as pancuronium (0.06 to 0.10 mg per kg IV) or rocuronium (0.6 to 1.2 mg per kg IV) is recommended over succinylcholine. Continued treatment of seizures, as indicated by electroencephalogram monitoring, is necessary during therapeutic paralysis. Diuresis and alkalinization of urine may be useful in preventing myoglobinuric renal failure for patients with rhabdomyolysis (see Chapter 200).

Physostigmine may be used safely and effectively in poisoned patients who have significant peripheral or central anticholinergic stigmata (i.e., agitated delirium) and normal PR and QRS intervals on ECG [43]. Physostigmine should be given slowly intravenously (0.02 mg per kg in children or 2 mg in adults) over 3 minutes. Alternatively, agitated delirium from the anticholinergic syndrome may be treated with benzodiazepines.

After stabilization, GI decontamination should be performed for patients with acute ingestions. Oral activated charcoal (1 g per kg) with or without a cathartic is the preferred method for the majority of the patients. Although gastric lavage may possibly benefit comatose patients who present within 1 hour of drug ingestion, it is not routinely recommended for neuroleptic overdose for which the mortality rate is very low [100]. If performed, gastric lavage should always be followed with activated charcoal administration. Because of decreased GI tract motility resulting from poisoning, decontamination (activated charcoal administration) may be of benefit many hours after overdose.

Although clinical improvement was reported during combined hemodialysis and charcoal hemoperfusion [101], the effect was transient, and measures to enhance the elimination of neuroleptic agents, such as diuresis, dialysis, and hemoperfusion, have not been shown to be pharmacokinetically effective [102,103]. Repeated oral doses of activated charcoal are of potential but unproved benefit. Use of multidose charcoal is not recommended and potentially harmful for patients who have developed an ileus.

The vast majority of the patients with neuroleptic poisoning recover completely within several hours to several days, depending on severity. Patients with intentional overdosage require psychiatric evaluation before discharge.

Patients with respiratory distress secondary to ADRs should be given supplemental oxygen. Those with buccolingual and torticollic crises should be given nothing by mouth, because doing so could precipitate choking. Because ADRs rarely result from an overdose, GI tract
decontamination is usually not indicated and may, in fact, be hazardous because of the potential for airway complications.

Administration of an anticholinergic agent readily reverses ADRs, presumably by restoring the balance between cholinergic and dopaminergic pathways in the basal ganglia [50]. Benztropine mesylate, 1 to 2 mg, or diphenhydramine, 50 to 100 mg, given intravenously over 1 to 2 minutes, can be used. Reversal of signs and symptoms usually occurs within a few minutes. In some cases, a second dose is needed for complete resolution. Benztropine appears to be more effective and is less likely to cause sedation and hypotension than diphenhydramine and is the preferred agent in adults [104]. Although benztropine is contraindicated in children younger than 3 years of age because of its anticholinergic effects [105], this is precisely the desired effect, and its administration in small doses (e.g., 0.25 to 0.50 mg) is appropriate in this situation. As an alternative, diphenhydramine (1 mg per kg IV) can be used. Benztropine and diphenhydramine can also be given intramuscularly, but it may take 30 to 90 minutes for the ADR to resolve when this route is used. Cases resistant to anticholinergic agents may respond to diazepam (0.1 mg per kg IV) or lorazepam (0.05 to 0.10 mg per kg IV).

Subsequent therapy with an oral anticholinergic agent should be continued for 48 to 72 hours. Without such therapy, the ADR may recur because it may take several days to eliminate completely the agent that caused it and the duration of action of drugs used to treat it is much shorter. In addition to benztropine and diphenhydramine, biperiden (2 mg one to three times a day), trihexyphenidyl (2 mg twice per day), or amantadine (100 to 200 mg twice per day) can be used for oral therapy. For reasons already noted, benztropine (1 to 2 mg twice per day) is the preferred agent for adults. Children younger than 3 years can be given diphenhydramine (1 mg per kg orally three or four times per day). Although patients who have had an ADR are at increased risk for future ADRs, those requiring continued antipsychotic therapy can usually continue or resume taking the offending agent provided they are also maintained on anticholinergic therapy. As an alternative, they can be switched to atypical antipsychotic with less dopaminergic-blocking activity.

Chapter 106

Beta-Blocker Poisoning

SHAN YIN • JAVIER C. WAKSMAN

Since 1958, when dichloroisoprenaline, the first β-adrenergic blocker, was synthesized, more than a dozen β-blockers have been introduced into the international pharmaceutical markets. Originally developed for the treatment of angina pectoris and dysrhythmias, β-blockers are now used in a wide variety of disorders. Intoxication may result from oral, parenteral, and even ophthalmic use.

PHARMACOLOGY

β-Blockers act by competitively inhibiting the binding of epinephrine and norepinephrine to β-adrenergic neuroreceptors in the heart (β₁), blood vessels, bronchioles (β₂), and other organs (Table 106.1). Binding to the β receptor (a G-protein–coupled receptor) activates phosphodiesterase and increases cytoplasmic cyclic adenosine monophosphate (cAMP). This in turn leads to modification of cellular processes and changes in ionic channel conductance. By reducing the activity of β receptors, the production of cAMP is decreased and β effect is diminished [1].

**β**-Blockers are usually rapidly absorbed after oral administration. The **β**-blocker dose required to produce a toxic effect is variable, depending on the sympathetic tone and metabolic capacity of the person and the pharmacologic properties of the particular **β**-blocker [1]. The first signs of toxicity may appear 20 minutes after ingestion, with peak effects typically occurring 1 to 2 hours after an immediate-release preparation overdose. Absorption of modified-release formulations may be erratic after an overdose, however, and clinical toxicity may be significantly delayed. The duration of toxicity may be several days [1].

The pharmacologic and pharmacokinetic properties of **β**-blockers are variable (Table 106.2). Cardioselectivity tends to be lost at high doses, and membrane-stabilizing effects, which are minimal at therapeutic doses, assume a more important role [1]. Membrane dysfunction may account for many of the central nervous system (CNS) and myocardial depressant effects in patients poisoned by membrane-active drugs such as propranolol. The half-life may be significantly prolonged in patients with decreased hepatic and renal perfusion [1]. Intrinsic heart, kidney, and liver disease as well as the concomitant use of drugs with similar activity increase the risk of toxicity.

superscript

Inhibits $\beta_2$ receptors (bronchial and vascular) at higher doses.

In elderly hypertensive patients with normal renal function, $t_{1/2}$ is variable (7–15 h).

CLINICAL TOXICITY

The major manifestations relate to the cardiovascular system and CNS. Respiratory, peripheral vascular, and metabolic (hypoglycemic and hyperkalemic) effects have been infrequently reported [1,2].

Patients with severe poisoning frequently present with hypotension and bradycardia. Tachycardia and hypertension have been reported with agents possessing intrinsic sympathomimetic activity, particularly pindolol [1]. Congestive heart failure and pulmonary edema have infrequently been reported and mainly occur in patients with underlying heart disease [3]. Electrocardiographic manifestations may include prolonged PR interval, intraventricular conduction delay, progressive atrioventricular heart block, nonspecific ST-segment and T-wave changes, early repolarization, prolonged QTc, and asystole [4–6]. Sotalol poisoning may result in ventricular tachycardia, torsade de pointes, ventricular fibrillation, and multifocal ventricular extrasystoles [7]. Labetalol, which also has mild β-receptor–blocking properties, may cause profound hypotension, possibly from decreased peripheral resistance.

Depression of the level of consciousness, ranging from drowsiness to coma with seizures, is another common feature of β-blocker poisoning. Significant CNS depression has been reported in the absence of cardiovascular compromise [1] or hypoglycemia and may be due to direct membrane effects [8]. Cerebral hypoperfusion, hypoxia, and metabolic or respiratory acidosis frequently contribute to CNS toxicity. β-Blockers with high lipid solubility (e.g., propranolol, penbutolol, metoprolol) appear more likely to cause CNS effects than those with low lipid solubility (e.g., atenolol) [9].

Bronchospasm is a relatively rare consequence of β-blocker poisoning and usually occurs among patients with preexisting reactive airway disease. In most instances, respiratory depression appears to be secondary to a CNS effect [10–11].

Although it does occur, hypoglycemia is not a common complication of β-blocker poisoning. It appears to be more common in diabetics, children, and uremic patients, and it is the consequence of impaired glycogenolysis and hepatic gluconeogenesis [12]. A blunted tachycardic response to hypoglycemia may occur among patients with β-blocker toxicity, although other symptoms of hypoglycemia appear unaffected.
DIAGNOSTIC EVALUATION

The history should include the time, amount, and formulation of drugs ingested; the circumstances involved; time of onset and nature of any symptoms; and treatments rendered before arrival, as well as underlying health problems. β-Blocker poisoning may be difficult to recognize, especially when multiple drugs have been ingested [1]. β-Blocker poisoning should be suspected in a patient in whom hypotension or seizures suddenly develop or who has bradycardia resistant to the usual doses of chronotropic drugs. Evaluation of patients with suspected β-blocker poisoning should begin with a complete set of vital signs, continuous cardiac rhythm monitoring, and a 12-lead electrocardiogram. Physical examination should focus on the cardiovascular, pulmonary, and neurologic systems. Vital signs and physical examination should be frequently repeated.

Serum drug levels may help confirm the diagnosis but are rarely available quickly enough to be clinically useful. In addition, differences in individual patient metabolism and sympathetic tone may make interpretation of blood levels difficult [1,2]. A serum and urine specimen can be saved for later analysis for forensic cases. Continuous cardiac rhythm monitoring, interpretation of 12-lead electrocardiograms, and measurement of oxygen saturation should be routine. Laboratory evaluation of symptomatic patients should include electrolytes, blood urea nitrogen, creatinine, bicarbonate, and glucose. Arterial blood gas and a chest film should be obtained as clinically indicated. Serum acetaminophen and aspirin levels should be obtained in patients with suicidal ideation.

The differential diagnosis of β-blocker toxicity includes antidysrhythmic drugs, calcium channel blockers, cholinergic agents, clonidine, digitalis, narcotics, sedative hypnotics, and tricyclic antidepressants. Anaphylactic, cardiogenic, hypovolemic, and septic shock should also be considered.
MANAGEMENT

Treatment is primarily supportive. This may include prompt endotracheal intubation and mechanical ventilation and management of life-threatening bradydysrhythmias, hypotension, bronchospasm, and seizures. These attempts should precede any measures (as described later) used to prevent or reduce drug absorption. A bedside glucose measure or, alternatively, an intravenous bolus of glucose (50 mL of D$_{50}$W in adults; 5 mL per kg of D$_{10}$W in children) as well as naloxone (2 mg in adults and children) should be considered for patients with altered mental status.

Activated charcoal is the preferred method for gastrointestinal decontamination. Gastric lavage has not been shown to improve outcomes after poisoning and should not be used routinely, but could be considered for recent life-threatening ingestions in patients who have not already vomited [13]. Whole-bowel irrigation with polyethylene glycol at a rate of 2 L per hour until the rectal effluent is clear may be considered for gastrointestinal decontamination in modified-release preparation overdoses.

Hypotension should be first treated with judicious intravenous crystalloid fluids. Because hypotension seldom responds solely to this treatment and because administration of high volumes (greater than 2 L) of intravenous fluids may pose a risk of developing pulmonary edema, the prompt use of inotropic drugs such as dopamine, dobutamine, epinephrine, norepinephrine, or phenylephrine is usually required [14]. Bradycardia from β-adrenergic antagonist poisoning seldom responds to atropine.

Calcium

The goal of calcium therapy is to increase extracellular calcium concentrations, thus increasing calcium influx through any unblocked calcium channels. Calcium has demonstrated effectiveness in animal models [15] and improvement has been reported for human cases [16]. However, responses are variable and often short-lived, and patients with significant toxicity usually fail to improve with calcium alone. Conduction disturbances, contractility, and blood pressure may be improved, but generally there is no increase in heart rate.

Calcium chloride compared to calcium gluconate contains three times the amount of elemental calcium on a milliequivalent basis (10% calcium chloride: 272 mg elemental calcium or 13.6 mEq per 1 g ampule; 10% calcium gluconate: 90 mg elemental calcium or 4.5 mEq per 1 g ampule).
However, it is recommended to only give calcium chloride via a central venous catheter. Calcium gluconate can be given via a peripheral line.

Optimum calcium dosing is not well established. Initial doses are generally given as boluses (10 to 20 mL of 10% calcium chloride, or 30 to 60 mL of 10% calcium gluconate). Additional boluses may be given every 10 to 20 minutes. Boluses should be given over a 5-minute period in conjunction with cardiac monitoring as rapid infusions have resulted in hypotension, atrioventricular dissociation, and ventricular fibrillation. The effects of boluses may be transient, and a constant infusion may be required. Infusions can be started at 0.4 mL/kg/h for calcium chloride and 1.2 mL/kg/h for calcium gluconate and titrated to effect. Additional boluses can be given as needed. Calcium levels should be monitored. Raising serum ionized calcium to 2 to 3 mEq per L improves canine cardiac performance in verapamil poisoning, and is a reasonable goal to attain. It may be necessary to continue therapy despite high serum calcium levels if the patient is only responding to calcium administration. Hypercalcemia can lead to renal failure and limb or mesenteric ischemia. It is recommended to stop calcium infusions if no beneficial effect is observed.

Glucagon

Although there are no controlled trials of glucagon for β blocker overdose in humans, glucagon has served as an effective agent for reversing hypotension and bradycardia in multiple case reports [17,18] and has a long history of use. Glucagon is typically given as an initial bolus of 3 to 5 mg for adults and 0.05 mg per kg for children. If there is no response to the initial bolus, a second bolus of 6 to 10 mg (0.10 mg per kg in children) can be given. Glucagon has a half-life of 20 minutes, so a continuous intravenous infusion of 1 to 10 mg per hour is recommended if the bolus is successful for improving hemodynamic parameters. The continuous infusion rate is set at the successful bolus rate (i.e., if a 5 mg bolus was successful, the infusion would be 5 mg per hour). Large total doses may be required. The dose should be tapered once the patient’s clinical condition improves. The mechanism by which glucagon produces positive inotropic and chronotropic effects on the heart is believed to be activation of the adenyl cyclase pathway, which converts adenosine triphosphate to cAMP through an independent receptor, changing membrane ion conductivity, altering calcium influx, and augmenting contractility even in the presence of complete β-adrenergic blockade [17].
Phosphodiesterase Inhibitors
The simultaneous use of multiple agents may be effective when a single agent fails. Although theoretically promising, phosphodiesterase inhibitors such as amrinone and milrinone, which inhibit the breakdown of cAMP to AMP, have not proven to be superior to glucagon for reversing the hemodynamic effects of β-blocker overdose in a canine model [19]. It has been suggested that phosphodiesterase inhibitors might be used in cases of β-blocker poisoning when adequate doses of glucagon are not available [19]. The phosphodiesterase inhibitor enoximone has been successfully used in cases of β-blocker overdoses [20].

Sodium Bicarbonate
A number of β-blockers (propranolol, carvedilol, pindolol, and acebutolol) also affect cardiac sodium channels producing membrane-stabilizing effects which may result in quinidine-like dysrhythmias (e.g., wide QRS complexes). This effect may respond to intravenous boluses of sodium bicarbonate, albeit in a canine model sodium bicarbonate was ineffective for treating propranolol toxicity that resulted in bradycardia, hypotension, and wide QRS intervals [21]. In a case report, sodium bicarbonate appeared to reverse QRS widening following an acebutolol overdose [22]. The recommended dose is 1 to 2 mEq per kg given as a rapid infusion over several minutes.

Hyperinsulin Euglycemia Treatment
High-dose insulin while maintaining euglycemia has been proposed as an antidote for β-blocker poisoning. Insulin is an inotropic agent, which may enhance response to catecholamines and reverse metabolic acidosis. Although results in animals remain encouraging [23,24], further studies are needed in humans. There are several human case reports where high-dose insulin resulted in improvements in hemodynamic parameters for isolated β blocker overdoses [25,26]. The general recommended starting dose is a 1.0 U per kg bolus followed by a continuous infusion of 0.5 to 1.0 U/kg/h. This rate can be titrated up to effect. A second intravenous infusion of D_{10}W or D_{25}W containing potassium chloride should be simultaneously administered to the insulin infusion at a rate sufficient to maintain the serum glucose and potassium concentrations in the normal range.

Vasopressin
The use of vasopressin for β blocker toxicity has been suggested. In one animal trial which compared vasopressin with glucagon as the treatment for β-blocker toxicity; vasopressin neither increased survival nor had a significant effect on any of the cardiac parameters tested compared to glucagon [27]. High-dose insulin treatment also improved survival when compared to vasopressin with epinephrine in a swine model [24].

**Lipid Emulsion**

The use of lipid emulsion has been suggested for the treatment of the cardiotoxic effects of local anesthetics. Various animal models of bupivacaine toxicity have demonstrated faster return of spontaneous circulation following treatment with lipid emulsion therapy [28,29] as well as improved cardiodynamic parameters when compared with epinephrine [30]. In a rabbit model, lipid emulsion successfully improved hypotension induced by propranolol when compared with placebo [31]. In a separate study of rats, pretreatment with lipid emulsion resulted in a significant reduction in QRS duration and a nonsignificant improvement in bradycardia induced by propranolol when compared with placebo [32]. Positive outcomes with the use of lipid emulsion were described for human case reports of bupivacaine [33,34], bupropion and lamotrigine [35], and quetiapine and sertraline overdoses [36]. There are no controlled trials of humans but in a number of case reports there was dramatic improvement [25,37]. The mechanism of how lipid emulsion may be beneficial is not completely understood. Possible explanations include the creation of lipid sink for fat-soluble drugs, augmentation of cardiac energy substrates, or the improvement in myocardial function by increasing intracellular calcium [37]. No standard dosing regimen exists. However, a loading dose of 1.5 mL per kg administered over 1 minute, repeated 1 to 2 times every 3 to 5 minutes as needed, is often used. If hemodynamic improvement is noted, the loading dose should be followed by a continuous infusion at a rate of 0.25 to 0.5 mL/kg/min. Further information can be found at www.lipidrescue.org.

**Extracorporeal Removal**

Although the efficacy of hemodialysis for acute β-blocker poisoning has not been studied in controlled clinical trials, it is theoretically useful for removing β-blockers that have a low volume of distribution, are not significantly protein bound, and are hydrophilic. This would include acebutolol, atenolol, nadolol, sotalol, and timolol. Hemodialysis appeared to be clinically useful in a number of case reports involving various β blockers [38,39]. Continuous Veno-Venous Hemo-Dia-Filtration (CVVHDF) was also successfully used for the treatment of a combined atenolol/nifedipine overdose [40].
Other Interventions

Transient blood pressure elevations caused by pindolol usually require no specific treatment. Short-acting agents such as nitroprusside should be used if marked blood pressure elevation occurs, especially if it is accompanied by organ ischemia. Ventricular dysrhythmias induced by sotalol have been treated with lidocaine, isoproterenol, magnesium, and cardioversion defibrillation [5]. Electrical cardiac pacing may be needed if bradycardia, hypotension, and heart block fail to respond to pharmacologic therapy [1], or if ventricular tachydysrhythmias associated with a prolonged QTc interval are difficult to control [5]. For severe overdoses, a pacemaker may not capture. If capture occurs, the increased heart rate may not increase blood pressure. Heart rates greater than 90 to 100 beats per minute significantly decrease diastolic filling time and may adversely affect inotropy. Intraaortic balloon pump counterpulsation and extracorporeal circulation [41] have been successfully used for cardiovascular support.

Patients with β-blocker overdose who have abnormal vital signs, altered mental status, or dysrhythmias on presentation should be admitted to an intensive care unit. If vital signs can be supported, complete recovery should be expected within 24 to 48 hours. Patients may be discharged after at least 6 hours of emergency department observation if they have ingested an immediate-release product, present with mild to absent toxicity and remain or become asymptomatic, have normal vital signs on discharge, and have received activated charcoal. These patients should be referred for psychiatric evaluation in the event of an intentional overdose or discharged in the care of a reliable observer after an accidental overdose. Any other symptoms mandate longer observation or admission. Because of the potential for delayed toxicity, prolonged observation is recommended after modified-release preparation overdose.
REFERENCES

INTRODUCTION

Accidental and intentional overdoses of calcium channel antagonists (CCAs) can be life threatening. CCAs consistently top the list of cardiovascular medications with the greatest proportion of deaths per exposure. Severely poisoned patients demonstrate cardiovascular collapse, but also metabolic derangements that appear similar to diabetic acidosis. Cardiovascular instability is often refractory to typical cardiotonic therapies and medication doses. There is no antidote for CCAs, and no controlled clinical studies to guide therapy. Treatment recommendations are therefore based on case series, case reports, animal studies, and expert opinion. Simultaneous use of multiple therapies is often required, and should be tailored to the patient’s cardiovascular and metabolic responses. Overall goals of treatment are to provide supportive care, optimize cardiovascular and metabolic function, and decrease drug absorption. If vital signs can be supported until the drug is metabolized or eliminated, most patients will survive without sequelae.
Available CCAs antagonize calcium influx through L-type voltage-sensitive channels, a specific type of calcium channel found in the heart, vascular smooth muscle, and pancreatic β-islet cells. Multiple physiologic functions are dependent on calcium influx through these channels.

In the cardiovascular system, calcium influx through L-type channels is responsible for the spontaneous pacemaker activity of the sinoatrial (SA) node and depolarization of the atrioventricular (AV) node. Other myocardial cells rely on calcium entry via L-type channels during the plateau phase of the action potential. Calcium entry during the plateau phase signals the release of additional calcium from intracellular stores allowing contraction to occur. The magnitude and duration of myocardial contraction is proportional to the magnitude and duration of calcium entry via L-type channels. Vascular smooth muscle tone is also maintained by a similar mechanism. Thus, therapeutic clinical effects of CCAs arise from blockade of L-type channels resulting in decreased cytosolic calcium levels. Depending on the class of CCA administered (see “Pharmacology” section), the clinical result is depression of SA node automaticity, AV node conduction, myocardial contractility, and vasodilation. The pathophysiologic effects of CCA overdose are essentially an exaggeration of pharmacologic effects, which lead to cardiovascular shock.

In addition to cardiovascular effects, CCA poisoning also produces a diabetogenic effect of hyperglycemia and acidosis. Insulin secretion is dependent on calcium influx into pancreatic β-islet cells. Although generally not a concern at therapeutic doses, calcium channel blockers (CCBs) decrease insulin secretion [1]. In canine models of verapamil-induced shock, hyperglycemia occurs but systemic insulin levels fail to increase [2–4]. Verapamil toxicity also produces systemic [4] and myocardial [3] insulin resistance. The cause of this resistance may be multifactorial involving decreased substrate delivery from poor perfusion, interference with calcium-dependent cellular insulin responsiveness and glucose uptake, and inhibition of calcium-stimulated mitochondrial dehydrogenases (i.e., pyruvate dehydrogenase) and glucose catabolism [4]. More recent evidence suggests CCAs interfere with cellular signaling, specifically recruitment of glucose transporter proteins (GLUTs) from the intracellular space to cell membranes [5,6]. These GLUTs are responsible for normal cellular uptake of glucose.

Verapamil toxicity also produces a state of hyperlacticacidemia because of a combination of tissue hypoperfusion and probably a defect in carbohydrate metabolism [4]. In stressed states such as CCA toxicity,
heart switches from preferentially using free fatty acids to carbohydrates (glucose and lactate) for energy production [2,3,7]. Although there is an abundance of circulating carbohydrates (e.g., glucose and lactate), they are essentially unavailable for use because of decreased insulin availability and systemic insulin resistance.

In essence, CCAs decrease cytosolic calcium levels resulting in desirable cardiovascular effects at therapeutic doses, and at toxic doses an exaggeration of those effects. Additionally, toxicity produces a vicious cycle where the myocardium is preferentially metabolizing carbohydrates, yet carbohydrate utilization is hindered by impaired insulin release and systemic insulin resistance.
Clinically available CCAs fall into one of three classes: phenylalkylamine (verapamil), benzothiazepine (diltiazem), and dihydropyridines (nifedipine and all other agents). At therapeutic doses, each class has differing affinities for myocardial tissues and vascular smooth muscle. Verapamil and diltiazem are potent inhibitors of SA node automaticity, AV node conduction, myocardial contractility, and cause modest vasodilation [8]. Verapamil affects the SA node, contractility, and vasodilation more than diltiazem [8]. This is probably why toxic ingestion of verapamil generally causes more deaths than other CCAs. Dihydropyridines are far more selective for vascular smooth muscle, and at therapeutic doses have very little effect on cardiac pacemaker cells or contractility [8]. In significant poisoning, this selectivity is however lost.

Pharmacologic properties of CCAs make extracorporeal removal of limited or no value. However, plasmapheresis was believed to be beneficial in several cases [9–11] and recently albumin dialysis with the Molecular Adsorbent Recirculating System was used successfully in three severe CCA poisonings [12]. Therapeutic half-lives of CCBs are variable, but in overdose can be prolonged [13]. The duration of toxicity for most cases is less than 24 hours, but has been reported to last 48 hours with sustained-release (SR) verapamil [14] and for more than 5 days with amlodipine [15].

Verapamil, diltiazem, nifedipine, and several of the newer dihydropyridines are available in both immediate-release (IR) and SR formulations. This information becomes important when considering how long to observe asymptomatic patients after an overdose. IR preparations produce signs or symptoms of toxicity within 6 hours of ingestion, whereas toxicity with SR products may be delayed 6 to 12 hours [16] or rarely longer [17]. Amlodipine, a dihydropyridine, has unique pharmacokinetics however. It is not a SR product, but has a late onset of peak effect and long half-life allowing for delayed and prolonged toxicity.

There is no accurate definition of a toxic dose. Patients have demonstrated significantly different effects at similar doses. Unintentional overdoses are common, but uncommonly result in significant effect. However, several adult patients have developed toxicity and death at doses less than maximum recommended daily doses [18]. Factors that could have contributed to this are advanced age, underlying medical conditions, additional medications, and chewing and swallowing SR preparations—essentially changing the pharmacokinetics into an IR formulation [18]. Generally, the most significant poisonings are large
intentional ingestions, but patients with significant underlying medical diseases or advanced age are prone to effects at lower doses.
CLINICAL MANIFESTATIONS

Cardiovascular effects are the primary manifestation of CCA poisoning. Alterations in mental status without significant hypotension should not be attributed to CCA ingestion. Minimally intoxicated patients, or those who present soon after ingestion, may demonstrate no signs of toxicity. All CCAs can cause hypotension in the setting of an overdose. However, the causes of the hypotension are typically an extension of the drugs’ therapeutic effects (i.e., dihydropyridines causing significant vasodilation with reflex tachycardia where verapamil and diltiazem slow SA and AV node conduction, decrease contractility, and cause vasodilation). Thus, for overdose, normal sinus rhythm or reflex tachycardia is commonly seen early in nifedipine poisonings, where sinus bradycardia, AV nodal blocks, and junctional rhythm are common with verapamil and diltiazem ingestions [16]. This selectivity may be lost in large overdoses such that dihydropyridine poisoning results in bradycardia and/or impaired cardiac conduction [15,16,19–21]. Although overdose experience with dihydropyridines other than nifedipine is limited [15,20–22], they would be expected to have effects similar to nifedipine. The exception may be amlodipine where toxic effects may be delayed [21].

Severe poisoning is characterized by hypotension and bradycardia [16,23–25], hyperglycemia [19–21,23,26–32], and metabolic acidosis [2,15,19,21,27,32,33]. Hyperglycemia is caused by the aforementioned alterations in insulin and carbohydrate homeostasis (see “Physiology and Pathophysiology” section). In fact, in a recent review of 40 CCA overdoses, the degree of hyperglycemia was the best predictor of composite end points of death, pacemaker requirement, or vasopressor requirement [34]. Dysfunctional carbohydrate metabolism and tissue hypoperfusion can result in hyperlacticacidemia. Additionally, tissue hypoperfusion can result in cerebrovascular accidents, seizures, renal failure, myocardial infarction, and noncardiogenic pulmonary edema [35].
DIFFERENTIAL DIAGNOSIS

CCA poisoning should be considered for any patient presenting with hypotension and bradycardia. Suspicions that the patient is poisoned with a CCA should be raised even further if there is associated hyperglycemia and acidosis. However, the differential diagnosis of a patient with hypotension and bradycardia includes other toxicologic causes such as β-blockers, digoxin and other cardiac glycosides, antidysrhythmics, and clonidine. However, nontoxicologic causes such as myocardial disease, hyperkalemia, sepsis, and hypothyroidism should also be considered.
MANAGEMENT

General

Management of a patient with CCA poisoning begins with airway management and maintenance of vital signs. Vascular access should be obtained, and continuous blood pressure and cardiac monitoring initiated. Preemptive intubation should strongly be considered for patients with significant ingestions or signs of toxicity because of the potential for rapid deterioration. Among bradycardic patients, administration of atropine before intubation may prevent vagal responses from laryngoscopy. An electrocardiogram (ECG) should be obtained. The presence of dysrhythmias or conduction disturbances, which may be as subtle as PR prolongation for some patients, should be noted. Measurements of renal function, electrolytes, complete blood counts, liver function tests, arterial blood gases, and acetaminophen, salicylate, and digoxin levels should be guided by the clinical picture and medical history.

Serum CCA levels are not routinely available and do not help with patient management, but may be necessary for confirmation of the diagnosis. For patients with severe or refractory hypotension, urinary and central venous catheterization are recommended to guide fluid and vasopressor therapy. Finally, early consultation with a medical toxicologist regarding medical therapy, and a cardiologist regarding pacemaker or intraaortic balloon pump placement, is recommended.

Gastrointestinal Decontamination

Definitive data regarding the utility of gastrointestinal decontamination for CCA overdoses are lacking, and all forms of decontamination carry potential risks. However, CCA overdoses can result in serious morbidity and mortality, such that potential benefits of decontamination may outweigh the risks. Risks and benefits should be considered on a case by case basis, and interventions necessary to maintain vital signs take precedence over decontamination. Aspiration is one of the main risks associated with decontamination. Thus, assurance of airway control prior to decontamination is necessary.

Activated charcoal should be administered to all significant ingestions. The greatest benefit of charcoal administration occurs within the first 2 hours after ingestion [36]. However, it may hold benefit, especially for SR preparations, up to 4 hours after ingestion [36]. Gastric lavage should not be used routinely, but considered for recent life-threatening ingestions in
patients who have not vomited [37]. Like laryngoscopy, lavage may theoretically increase vagal tone and exacerbate bradydysrhythmias. Administration of atropine prior to insertion of the lavage tube may ameliorate these effects.

Large ingestions of SR preparations may provide a gastrointestinal depot of drug causing recurrent cardiovascular compromise, or rise in serum drug levels up to 18 hours after initial decontamination [17,24,27,30,38,39]. A rise in serum amlodipine levels has been demonstrated 24.5 hours after ingestion—approximately 22 hours after decontamination [40]. Therefore, repeat charcoal doses or whole-bowel irrigation (WBI) with polyethylene glycol should be considered for large ingestions of SR products in patients with functioning gastrointestinal tracts [35]. Repeat charcoal dosing has also been recommended for large overdoses of IR products [13]. One or two additional doses of activated charcoal (0.5 g per kg without cathartic) separated by 2 to 4 hours may be sufficient. Because of the large volumes necessary, polyethylene glycol WBI should be administered via a nasogastric tube (0.5 L per hour for small children and 1 to 2 L per hour for adults). However, it may be prudent to withhold WBI in patients with hemodynamic compromise [41].

Cardiovascular Support

Hypotension should initially be treated with intravenous crystalloids with close monitoring for fluid overload. Although usually ineffective for severe poisoning [16,17,23,30], atropine should be given for symptomatic bradycardia. Treatment beyond general supportive care, intravenous fluids, and atropine will depend on the clinical situation. Seriously poisoned patients may require rapid simultaneous administration of multiple therapies. Transvenous pacing may be attempted, but in significant poisoning there may be failure to capture, and blood pressure may not improve despite an increase in heart rate [16,17].

Vasopressors

The exact sequence of pharmacologic therapies has not been studied. However, health care providers generally have the greatest familiarity with dosing and administration of vasopressor agents. Thus, these agents can often be initiated rapidly and may improve cardiovascular instability. Ideally, an agent with both α-1 and β-agonist effects should be instituted. Improvements have been noted with dopamine, dobutamine,
norepinephrine, isoproterenol, and epinephrine. However, no specific agent has demonstrated superiority, so it is reasonable for clinicians to start with the agent they are most familiar with. There is scant information regarding vasopressin utility in CCA poisoning, but based on available data, it should not be used as monotherapy in CCA poisoning. Animal models have demonstrated either no improvement in mean arterial pressure [42] or decreased survival [43] with vasopressin compared to saline controls. However, there was improvement in systemic vascular resistance and blood pressure after vasopressin was administered to two patients unresponsive to multiple other therapies [44].

Multiple simultaneous vasoactive agents may be required depending on the hemodynamic response, and require doses much higher advanced cardiac life support (than ACLS) -based doses [45]. Because vasopressors can result in tachydysrhythmias, increased myocardial oxygen consumption and vasospastic events, these agents should be the first to be weaned from a patient who has stabilized.

Hyperinsulinemic Euglycemia

Hyperinsulinemic euglycemia (HIE) refers to the administration of high-dose regular insulin while maintaining normal serum glucose levels. HIE is thought to overcome the CCA-induced compromise of cardiovascular carbohydrate uptake, thus improving hemodynamic embarrassment. The exact mechanisms underlying these actions still remain controversial [46], but may be best described in the following animal studies.

Four animal studies (mongrel dogs) of HIE in verapamil poisoning [2,3,7,47] have been rated as very good to excellent quality by an expert panel [45]. Where survival from poisoning was measured, 100% of animals treated with insulin survived [47]. However, survival with epinephrine [2,47], glucagon [2,47], and calcium [2] was 33%, 0%, and 17%, respectively. Insulin also increased the mean lethal dose of verapamil and time to death compared to epinephrine and glucagon [7]. In these studies, HIE improved and sustained cardiac contractility, systolic and diastolic function, and systemic and cardiac blood flow compared to calcium, glucagon, and epinephrine [2,3,7,47]. Insulin improved myocardial metabolism and function without increasing myocardial oxygen consumption [3,7]. Epinephrine, glucagon, and calcium however contribute to oxygen wasting [2].

The first report of HIE therapy, published in 1999, included five CCA poisoned patients who failed to respond to other therapies [22]. The benefit of HIE was striking. Insulin dosing included a 10 to 20 IU bolus with a 25 g bolus of glucose followed by an infusion of insulin 0.1 to 1.0 IU/kg/h (mean 0.5 IU/kg/h) and dextrose 10 to 75 g per hour (mean 28.4
g per hour). One patient had failed to improve with respiratory support, crystalloids, atropine, calcium, and glucagon. After initiation of HIE, blood pressure improved, complete heart block resolved, and ejection fraction increased from 10% to 30%. Many other cases have been published and the clinical data supporting HIE have been reviewed [46,48]. The data provide multiple examples of CCA poisoned patients improving with HIE therapy after failing treatments such as atropine, pacing, vasopressors, calcium, glucagon, and phosphodiesterase inhibitors (PDI).

Clinical improvement from HIE is gradual and may take 30 minutes or more. However, one patient who failed to respond to dopamine, norepinephrine, calcium, and glucagon showed a dramatic response within 15 minutes of receiving a 10-fold dosing error of insulin (1,000 IU) [49]. Patients responding to insulin therapy demonstrate improved blood pressure, myocardial contractility, and metabolic acidosis, whereas effects on bradycardia and cardiac conduction are variable [46].

Failures of HIE therapy have also been reported. Our lack of knowledge regarding optimum dosing of insulin has been suggested as a reason for failures with HIE [50]. Canine studies of verapamil toxicity employed insulin doses of up to 16 IU/kg/h, but a dose-response relationship for insulin has not been determined [50]. The timing of HIE administration may also be a consideration. In several failures HIE was initiated multiple hours after ingestion when significant hemodynamic compromise was already present. This suggests a threshold point in CCA poisoning where there may be no beneficial intervention once that threshold is crossed. Therefore, HIE should be instituted as soon as hemodynamic abnormalities occur and well before profound shock supervenes. Although an optimal dosing scheme has yet to be established, a rational starting point is an initial insulin bolus of 1 IU per kg with 25 g of dextrose, followed by an infusion at 1 U/kg/h and 0.5 g/kg/h of dextrose [35,46]. It is believed supraphysiologic insulin doses are required to overcome CCA inhibition of insulin responsive GLUTs (see “Physiology and Pathophysiology” section) [5]. Increasing the insulin dose may be of benefit if response is insufficient. Doses up to 10 IU/kg/h have been recommended by some authors [51]. Serum glucose should be monitored closely and dextrose infusions adjusted to maintain normal ranges.

Hypoglycemia and hypokalemia, expected adverse effects of HIE, can be easily detected and treated. The safety of HIE therapy was demonstrated in a prospective observational study [52]. Serum glucose and potassium were monitored every 30 minutes until stable and then 1 to 2 hourly thereafter. Out of seven patients, only one episode of hypoglycemia (43.5 mg per dL) occurred (occurring 33.5 hours after ingestion when the maximal effects of CCA-induced insulin resistance would be waning). Hypokalemia (2.5 to 3.5 mmol per L) occurred in two
patients without any clinical significance. Mild hypokalemia may actually provide a beneficial effect in CCA poisoning [22,32]. The effects of insulin may last for hours after discontinuing an infusion. Thus, ongoing glucose monitoring is necessary even after insulin is discontinued. Aggressive correction of insulin-induced hypokalemia is unnecessary unless the patient is symptomatic or potassium falls below an arbitrarily suggested level of 2.5 mEq per L [22].

**Calcium**

The goal of calcium therapy is to increase extracellular calcium concentrations thereby increasing calcium influx through any unblocked calcium channels. Calcium has demonstrated effectiveness in animal models [53], and improvement has been reported in human cases [17,54]. However, responses are variable and often short-lived, and patients with significant toxicity often fail to improve with calcium alone [16,23]. Conduction disturbances, contractility, and blood pressure may be improved, but generally there is no increase in heart rate [16,23,30]. Optimum dosing has yet to be established, and 4.5 to 95.3 mEq were used in one case series without an identifiable dose–response [16].

Calcium chloride contains three times the amount of elemental calcium of calcium gluconate (10% calcium chloride: 272 mg elemental calcium or 13.6 mEq per 1 g ampule; 10% calcium gluconate: 90 mg elemental calcium or 4.5 mEq per 1 g ampule). The higher elemental calcium content in calcium chloride also poses a greater risk for tissue injury should extravasation occur. Thus, calcium chloride administration via central venous access is generally preferred.

Optimum calcium dosing is not well established. Initial doses are generally given as boluses (10 to 20 mL of 10% calcium chloride or 30 to 60 mL of 10% calcium gluconate). Additional boluses may be given every 10 to 20 minutes. Some authors suggest more aggressive dosing of 1 g every 2 to 3 minutes until clinical response is seen [31]. Boluses should be given over a 5-minute period in conjunction with cardiac monitoring as rapid infusions have resulted in hypotension, AV dissociation, and ventricular fibrillation. The effects of boluses may be transient, and a constant infusion required [21,31]. Infusions can be started at 0.4 mL/kg/h for calcium chloride and 1.2 mL/kg/h for calcium gluconate and titrated to effect. Additional boluses can be given as needed. Calcium levels should be monitored. One author recommends maintaining serum ionized calcium levels approximately twice normal [55]. Raising serum
ionized calcium to 2 to 3 mEq per L improves canine cardiac performance in verapamil poisoning [2,53], and is a reasonable goal to attain. It may be necessary to continue therapy despite high serum calcium levels if the patient is only responding to calcium administration. Significantly poisoned patients have tolerated high serum calcium levels without untoward effect [39,54], including one patient who obtained a peak serum calcium level of 23.8 mg per dL [17]. However, a patient in another report achieved a peak calcium level of 32.3 mg per dL and developed auric renal failure and eventually died [56]. Repeated calcium dosing or infusions should be discontinued if no beneficial effect is observed.

**Glucagon**

Glucagon possesses both inotropic and chronotropic effects, and experimentally increases heart rate, cardiac output, and reverses AV nodal blocks in CCA poisoning [57]. Several case reports noted improvement with glucagon therapy [26,38], but failures are also reported [30,32]. Five to 10 mg (150 μg per kg) given intravenously over 1 to 2 minutes is a typical starting dose [57]. Cardiovascular effects of glucagon last only 10 to 15 minutes [58], so repeat boluses may be required every 5 to 10 minutes followed by a continuous infusion of 2 to 10 mg per hour (50 to 100 μg/kg/h) [57]. Glucagon is a potent emetic [58], so airway control should be ensured before administration. Hyperglycemia and hypokalemia may also be observed with glucagon administration [58].

**Phosphodiesterase Inhibitors**

PDI such as inamrinone (amrinone) and milrinone increase cytosolic calcium and improve inotropy. PDI have been used in combination with other therapies to treat CCA poisoned patients [28,29], and appear to be effective in animal models [59,60]. However, they can be difficult to titrate and cause vasodilation and hypotension so are not generally recommended.
RESCUE AND EXPERIMENTAL THERAPIES

Nonpharmacologic Therapies

If available, intraaortic balloon counterpulsation, extracorporeal membrane oxygenation (ECMO), or cardiopulmonary bypass [30] may provide a bridge to survival in patients unresponsive to other therapies.

Pharmacologic Therapies

4-Aminopyridine

4-Aminopyridine is an orphan drug used to treat spinal cord injury and multiple sclerosis. It improves contractility by indirectly increasing intracellular calcium levels and has shown benefit in animal studies of verapamil toxicity [61,62] and in one human case report [63]. Unfortunately, it causes seizures and has a narrow therapeutic index. It may be considered if all other treatments are failing.

Methylene Blue

Methylene blue inhibits the nitric oxide–cyclic guanosine monophosphate pathway and has been used to treat vasodilatory shock such as in sepsis and anaphylaxis. A recent case report demonstrated hemodynamic improvement after methylene blue administration in a patient with vasodilatory shock from amlodipine poisoning who was failing HIE, dopamine, and norepinephrine [64]. The dose used was 2 mg per kg over 20 minutes followed by 1 mg/kg/h. Response to methylene blue may be specific to amlodipine as it is reported to have effects on the nitric oxide pathway, but in another recent amlodipine ingestion, there was no notable response to methylene blue administration [65]. A recent animal model of amlodipine poisoning did not show a survival benefit from methylene blue compared to saline [64]. However, mean arterial pressure, heart rate, and time to death were increased in animals receiving methylene blue. Therefore, its use may be considered in CCA poisoned patients with vasodilatory shock who are failing other therapies with the understanding that adverse effects such as hemolysis as potentiation of serotonin syndrome can occur [66].

Intravenous Lipid Emulsion

Perhaps the most novel therapy for CCA poisoning is intravenous lipid
emulsion (ILE). Intravenous lipids have traditionally been used as a source of free fatty acids in parenteral nutrition. A chance observation led to the finding that ILE is beneficial in the treatment of local anesthetic-induced cardiac arrest [67]. Multiple animal studies followed demonstrating dramatic results with ILE for local anesthetic toxicity. This led to the incorporation of ILE into anesthesiology guidelines for the treatment of local anesthetic cardiotoxicity, but ILE has now been used to treat poisoning from over 30 different agents including CCAs [68]. Animal studies have demonstrated prolonged survival with ILE in CCA poisoning [69–71]. In a case series of severely ill overdoses, ILE was thought to have facilitated survival in 55% of patients who, they believe, would otherwise have died [72]. Six of the nine patients in this series were poisoned with CCAs. Three of those six survived.

Proposed mechanisms of ILE therapy include creation of a “lipid sink” where lipid soluble toxins are sequestered, augmenting cardiac energy supplies, and increasing intracellular calcium in cardiac myocytes [73].

Lipemic serum is an obvious adverse effect of ILE which interferes with many laboratory results and may interfere with ECMO [74] and renal replacement circuits [75]. Although not definitively causative, more significant adverse effects, such as acute respiratory distress syndrome and pancreatitis [76,77], and even cardiac arrest [78], have been temporally related to ILE administration.

Clinical evidence supporting ILE for CCA poisoning is currently limited and likely suffers from reporting bias. However, it still should be considered for patients who are failing adequate doses of other more traditional therapies. Optimum ILE dosing has not been established but one of the most commonly used regimens can be found at www.lipidrescue.org.
DISPOSITION

Patients with signs or symptoms of toxicity require intensive care unit admission. Disposition of asymptomatic patients depends on the formulation ingested. Patients with large or intentional ingestions of SR products or amlodipine should undergo appropriate decontamination and 24 hours of observation in a closely monitored setting. Patients with small unintentional ingestions of SR products may be medically cleared after appropriate decontamination if they remain asymptomatic with normal vital signs and ECGs for 8 to 12 hours. Close attention should be paid to subtle ECG signs of toxicity such as PR prolongation. Patients ingesting non-SR products may be cleared after 6 to 8 hours of observation if normal vital signs and ECGs are maintained.

Cardiac glycosides (CGs) are naturally occurring substances whose medicinal benefits have been recognized for centuries [1]. Digoxin is the major CG used for medicinal purposes today. Although its use throughout the United States has steadily declined in recent years, digoxin is still used in the treatment of congestive heart failure and atrial fibrillation [2]. Digoxin is responsible for most cases of CG poisoning; however, exposure to plant (i.e., dogbane, foxglove, lily of the valley, oleander, red squill, and Siberian ginseng), animal sources (i.e., Bufo toad species), and topical aphrodisiacs can also result in serious toxicity [3–5].

PHARMACOLOGY

Digoxin exerts a positive inotropic effect, thereby enhancing the force of myocardial contraction. Direct effects of digoxin include prolongation of the effective refractory period in the atria and the atrioventricular (AV) node, which diminishes the conduction velocity through those regions. CGs are readily absorbed through the gastrointestinal tract; digoxin has up to 80% bioavailability [6]. Digoxin has a volume of distribution ($V_d$) of 5.1 to 7.4 L per kg [7] and a half-life of 36 to 48 hours [8]. The generally accepted therapeutic serum concentration range for digoxin is 0.8 to 2.0 ng per mL for inotropic support in patients with left ventricular dysfunction. Higher concentrations (1.5 to 2.0 ng per mL) may be needed for ventricular rate control in patients with atrial dysrhythmias. Digoxin is primarily eliminated by renal excretion. In patients with renal dysfunction, digoxin clearance is reduced. Serum digoxin concentrations can be altered by numerous drug interactions [9–11].

Toxicity results from an exaggeration of therapeutic effects [6]. CGs bind to and inactivate the sodium–potassium adenosine triphosphatase pump ($Na^+–K^+$-ATPase) on cardiac cell membranes. This pump maintains the electrochemical membrane potential, vital to conduction...
tissues, by concentrating Na\(^+\) extracellularly and K\(^+\) intracellularly. When Na\(^+\)–K\(^+\)-ATPase is inhibited, the Na\(^+\)–calcium exchanger removes accumulated intracellular sodium in exchange for calcium. This exchange increases sarcoplasmic calcium and is the mechanism responsible for the positive inotropic effect of digitalis. Intracellular calcium overload causes delayed afterdepolarizations and gives rise to triggered dysrhythmias. Increased vagal tone and direct AV depression may produce conduction disturbances. The decreased refractory period of the myocardium increases automaticity.
Differences between the presentations of patients with CG poisoning due to a single acute ingestion and those with chronic toxicity resulting from excessive therapeutic doses are illustrated in Table 108.1. Diagnosing chronic CG toxicity is difficult because the presentation may mimic more common illnesses, such as influenza or gastroenteritis. Patients with chronic CG toxicity may present with constitutional, gastrointestinal, psychiatric, or visual complaints that may not be recognized as signs of digitalis toxicity. Symptoms most commonly reported include fatigue, weakness, nausea, anorexia, and dizziness [12]. Neuropsychiatric signs and symptoms include headache, weakness, vertigo, syncope, seizures, memory loss, confusion, disorientation, delirium, depression, and hallucinations [13]. The most frequently reported visual disturbances are cloudy or blurred vision, loss of vision, and yellow-green halos or everything appearing “washed in yellow” (xanthopsia) [14].

Adapted and combined from references [1,12,13,15,29].

Cardiac manifestations of CG toxicity are common and potentially life threatening. An extremely wide variety of dysrhythmias has been reported [15,16]. Dysrhythmias frequently associated with CG toxicity include premature ventricular contractions, paroxysmal atrial tachycardia or atrial fibrillation with a conduction block, junctional tachycardia, sinus bradycardia, AV nodal blockade, ventricular tachycardia, and ventricular fibrillation. Atrial tachycardia (enhanced automaticity) with variable AV block (impaired conduction), atrial fibrillation with an accelerated or slow junctional rhythm (regularization of atrial fibrillation), and fascicular tachycardia are highly suggestive of CG toxicity [17,18]. Bidirectional ventricular tachycardia, a narrow-complex tachycardia with right bundle-branch morphology, is highly specific, but not pathognomonic, for digitalis toxicity [15].

Myocardial disease, myocardial ischemia, and metabolic [19] or electrolyte disturbances, such as hypokalemia, hypomagnesemia, and hypercalcemia [8], increase the risk of toxicity. The elderly are at increased risk, whereas renal impairment, hepatic disease, hypothyroidism, chronic obstructive pulmonary disease, and drug interactions alter sensitivity to CGs [1].
Essential laboratory tests include serum digoxin concentrations, electrolytes, blood urea nitrogen, creatinine, calcium, magnesium, and an electrocardiogram. Additional laboratory tests should be obtained as clinically indicated. Serum digoxin concentrations can assist in the diagnosis of CG poisoning but must be interpreted carefully [18]. A therapeutic concentration does not exclude poisoning, as predisposing factors can cause an individual to become poisoned despite a concentration within the therapeutic range. Conversely, high serum digoxin concentrations after an acute ingestion do not always indicate toxicity [20]. Digoxin follows a two-compartment model of distribution, with relatively rapid absorption into the plasma compartment and then slow redistribution into the tissue compartment [8]. Serum digoxin concentrations most reliably correlate with toxicity when obtained after distribution is complete, which occurs 6 hours or more after oral or intravenous digoxin administration.

Naturally occurring digitalis glycosides from plants and animals can cross-react with the digoxin assay. The degree of cross-reactivity is unknown, and because the assays are not calibrated for nondigoxin glycosides, the measured value cannot be reliably interpreted [5]. A false-positive digoxin assay (usually a concentration below 3 ng per mL) may occur in neonates and patients with renal insufficiency, liver disease, and pregnancy because of endogenous digoxin-like immunoreactive factors [21–23].

Hyperkalemia may be a better indicator of end-organ toxicity than the serum digoxin concentration in the acutely poisoned patient [24]. In contrast, hypokalemia and hypomagnesemia are commonly seen in the chronically intoxicated patient, presumably as a result of concomitant diuretic use.
MANAGEMENT

The management of CG poisoning includes supportive care, prevention of further drug absorption, appropriate administration of digoxin antibody fragments, and safe disposition. Meticulous attention to supportive care and a search for easily correctable conditions, such as hypoxia, hypoventilation, hypovolemia, hypoglycemia, and electrolyte disturbances, are top priorities. All patients should have vascular access established and continuous cardiac monitoring. Patients with clinical toxicity or elevated serum digoxin concentrations in the setting of suspected overdose require close monitoring and often warrant intensive care unit (ICU) admission.

Prevention of further drug absorption should be addressed after life support measures have been initiated. Gastric lavage has little, if any, benefit in the management of digoxin toxicity. Activated charcoal effectively binds CGs, and multiple doses of activated charcoal enhance intestinal digoxin elimination after oral and intravenous digoxin administration [25].

Conventional treatment of bradydysrhythmia, including the use of atropine, isoproterenol, and cardiac pacing, may not be effective for bradycardia due to CG poisoning. Atropine has been used with variable success in patients with digitalis toxicity exhibiting AV block [26]. Although isoproterenol may increase ventricular ectopy and cardiac tissue may be unresponsive to electrical pacing, the fibrillation threshold may be lowered, and the pacing wire itself may induce ventricular fibrillation [27]. Digoxin-specific antibody fragments (Fab) are first-line therapy in patients with symptomatic bradycardia [28].

Digoxin-specific antibody Fab is also the treatment of choice for life-threatening ventricular dysrhythmias. If this therapy is not immediately available, phenytoin and lidocaine, which depress increased ventricular automaticity without slowing AV nodal conduction, should be the initial therapy [18,29]. Amiodarone was successful in two cases refractory to other antidysrhythmics [30,31]. Intravenous magnesium, 2 to 4 g (10 to 20 mL of a 20% solution) over 1 minute, may also be useful [32]. Quinidine and procainamide are contraindicated in digitalis toxicity because they depress AV nodal conduction and may worsen cardiac toxicity [1]. Electrical cardioversion of the digitalis-toxic patient should be performed with extreme caution and considered a last resort. A low-energy setting (e.g., 10 to 25 W per second) should be used and preparations made to treat potential ventricular fibrillation [29].

Hyperkalemia is common in patients with acute digoxin poisoning, and empiric administration of supplemental potassium should be avoided
This increase in serum potassium concentration reflects a change in potassium distribution and not an increase in total body potassium stores. Significant hyperkalemia due to acute overdose is another indication for digoxin-specific antibody Fab. If digoxin-specific antibody Fab are not immediately available and the patient has hyperkalemia with associated electrocardiogram changes, intravenous glucose and insulin, sodium bicarbonate, continuous inhaled β agonists such as albuterol (if there is no tachydysrhythmia or ectopy), and sodium polystyrene sulfonate should be administered. The use of intravenous calcium to treat hyperkalemia in CG toxic patients remains controversial and has been previously avoided by many clinicians because additional calcium has been reported to enhance cardiac toxicity [19]. However, recently authors have questioned this dogma—citing animal studies and human case reports that document no untoward effects when calcium is administered in the setting of CG toxicity—and recommend the use of intravenous calcium in those patients with CG toxicity who have life-threatening hyperkalemia with significant changes on the electrocardiogram such as loss of P waves or widening of the QRS [34]. Hemodialysis may be of benefit in a CG-poisoned patient with renal failure and hyperkalemia.

Supplemental potassium may be beneficial in chronic digitalis toxicity when diuretic-induced hypokalemia is a factor. Potassium should be administered cautiously, as renal dysfunction may be the cause of digitalis toxicity. Hypomagnesemia is common in patients with chronic CG toxicity, and supplemental magnesium is recommended for such patients [35].

Digoxin-specific antibody Fab therapy is indicated for patients with dysrhythmias that threaten or result in hemodynamic compromise and patients with serum potassium greater than 5.0 to 5.5 mEq per L after acute CG overdose [36]. Chronically poisoned patients who are asymptomatic can often be managed with discontinuation of digoxin and close observation. However, the threshold for treatment with digoxin-specific antibody Fab should be lower in those patients with signs of cardiac toxicity (e.g., severe bradycardia with second- or third-degree AV block), or who have predisposing conditions such as chronic pulmonary disease, hypokalemia, hypothyroidism, renal dysfunction, or underlying cardiac disease [12,37]. Animal studies and case reports suggest digoxin-specific antibody Fab may be an effective treatment for patients poisoned by plant or animal sources of CG [3,5].

Digoxin-specific antibody Fab can reverse digitalis-induced dysrhythmias, conduction disturbances, myocardial depression, and
hyperkalemia. In a multicenter study, 90% of patients with digoxin or digitoxin toxicity had a complete or partial response to digoxin-specific antibody Fab therapy [36]. Complete resolution of toxicity occurred in 80% of the patients, and partial response occurred in 10%. The time to initial response from end of digoxin-specific antibody Fab infusion was within 1 hour (mean 19 minutes), and the time to complete response was 0.5 to 6.0 hours (mean: 1.5 hours). However, the majority of these patients were acutely poisoned and it is possible that chronically poisoned patients may respond differently. Treatment failures have been attributed to inadequate or delayed dosing, moribund clinical state before digoxin-specific antibody Fab therapy, pacemaker-induced dysrhythmias, and incorrect diagnosis of digitalis toxicity [36,38].

Digoxin-specific antibody Fab dosage (number of vials) calculations are based on the serum digoxin concentration or estimated body load of digoxin. It is assumed that equimolar doses of antibody fragments are required to achieve neutralization [39]. A 40-mg dose of digoxin-specific antibody Fab (one vial) binds 0.6 mg of digoxin. The number of vials required can be calculated by dividing the total body burden by 0.6. The body burden can be estimated from the milligram amount of an acute ingestion or by multiplying the post-distribution serum digoxin concentration (ng per mL) by the volume of distribution of digoxin (= 5.6 L per kg times the body weight in kg) and dividing by 1,000.

In the largest prospective study of Fab for digoxin poisoning (n = 150, mean serum concentration of 8 ng per mL), the dose of Fab required to reverse digoxin toxicity was five vials with a range from 3 to 20 vials [36]. A severely toxic patient in whom the quantity ingested acutely is unknown should be given 5 to 10 vials at a time and the clinical response observed. If cardiac arrest is imminent or has occurred, the dose can be given as a bolus. Otherwise, it should be infused over 30 minutes. In contrast, patients with chronic therapeutic overdose often have only mildly elevated digoxin concentrations and respond to one to two vials of digoxin-specific antibody Fab. The recommended dose for a given patient can be determined using the tables in the package insert or by contacting a regional poison center or toxicology consultant.

The dose of digoxin-specific antibody Fab needed to treat nondigoxin CG poisoning is unknown but likely to be greater than that necessary for digoxin poisoning. Starting with 5 to 10 vials and repeating this dose as necessary is a reasonable approach.

Free digoxin concentrations are decreased to zero within 1 minute of digoxin-specific antibody Fab therapy, but total serum digoxin concentrations may be markedly increased [36,40]. Because most assay methods measure total (bound and free) digoxin, very high digoxin concentrations are seen after digoxin-specific antibody Fab treatment, but they have no correlation with toxicity [40]. Serum concentrations
may be unreliable for several days after digoxin-specific antibody Fab therapy [41].

The digoxin–Fab complex is excreted in the urine and has a half-life of 16 to 20 hours [42]. In patients with renal failure, elimination of the digoxin–Fab complex is prolonged and free digoxin concentrations gradually increase over 2 to 4 days after digoxin-specific antibody Fab administration [43]. In one report of 28 patients with renal impairment given digoxin-specific antibody Fab, only one patient had recurrent toxicity, which occurred 10 days after digoxin-specific antibody Fab treatment and persisted for 10 days [44]. Monitoring of free digoxin concentrations may be beneficial for titrating effect in those patients reliant on the inotropic action of digoxin, detecting rebound toxicity in patients with renal impairment, assessing the need for further treatment with digoxin-specific antibody Fab, or in guiding the reinstitution of digoxin therapy [45]. Hemodialysis has not been reported to enhance digoxin–Fab complex elimination.

Digoxin-specific antibody Fab therapy has been associated with mild adverse drug events such as rash, flushing, and facial swelling [36,38]. However, neither acute anaphylaxis nor serum sickness has been described [38]. Before digoxin-specific antibody Fab administration, an asthma and allergy history should be obtained. Intradermal skin testing should be considered in high-risk patients. If a patient with a positive skin test is dying, however, the risk–benefit ratio obviously favors treatment [38]. A precipitous drop in the serum potassium, recurrence of supraventricular tachydysrhythmias previously controlled by digoxin, and development of cardiogenic shock in a patient dependent on digoxin for inotropic support have all been associated with digoxin-specific antibody Fab therapy [36]. Recurrent toxicity has been observed in 3% of patients [38]. In most, it was attributed to an inadequate initial dose of digoxin-specific antibody Fab dosing and reversed with a repeat dose.

Patients who receive digoxin-specific antibody Fab require continued monitoring in an ICU for at least 24 hours. Those with elevated drug concentrations resulting from chronic therapy who are hemodynamically stable can be observed on a telemetry unit. Discontinuing the use of digoxin or decreasing the dose, modifying predisposing factors, and closely monitoring subsequent therapy are necessary to avert further toxic episodes. Patients with suicidal ingestions should have a psychiatric evaluation before discharge.
REFERENCES

Cholinergic (acetylcholinesterase [AChE] inhibitor) agents are used in medicine, as insecticides, and as “nerve agent” chemical weapons. Many poisonings result from accidental dermal contamination during agricultural use of pesticides [1]. The majority of suicide attempts are ingestions [2]. Food-borne exposures have produced epidemics such as “Ginger Jake paralysis” (delayed neuropathy) because of contamination of an alcoholic drink with triorthocresyl phosphate [3] and an epidemic affecting over 2,000 people with mild-to-moderate symptoms related to the use of aldicarb on watermelons; an insecticide that is no longer made in the United States and will no longer be available in 2018 [4].

PHARMACOLOGY

Cholinesterase inhibitors act primarily by blocking the active site of AChE. Organophosphates (OPs) form a covalent phosphate linkage at the enzyme active site. Enzyme regeneration occurs by either de novo synthesis, hydrolysis of the serine–organophosphorus bond, or oxime-aided reactivation. Over a period of time, in a process that is agent-dependent, the OP molecule “ages” on the enzyme and is resistant to reactivation by oxime therapy. Carbamates are reversible inhibitors of AChE, occupying but not modifying the catalytic region of the enzyme. AChE activity is restored when the carbamate spontaneously leaves the enzyme’s active site [5]. Reversible AChE inhibitors such as tacrine, rivastigmine, donepezil, and galantamine have been used for the treatment of Alzheimer’s dementia. The characteristics and treatment of exposure to these products are covered at the end of this chapter.
Inhibition of AChE allows the neurotransmitter acetylcholine to accumulate and remain active in the synapse, resulting in sustained depolarization of the postsynaptic neuron or effector organ. This effect occurs in the central nervous system (CNS) as well as at muscarinic sites in the peripheral nervous system, nicotinic sites in the sympathetic and parasympathetic ganglia, and nicotinic sites at the neuromuscular junction. In general, effects at muscarinic sites are sustained, whereas nicotinic sites are stimulated and then depressed (hyperpolarization block). Signs and symptoms of cholinergic toxicity typically appear when 60% to 80% of cholinesterase activity has been inhibited [6]. The pharmacologic and toxicologic effects of the AChE inhibitor are an extension of their mechanism of action (Table 109.1).

\(^a\)Relative contributions of nicotinic and muscarinic receptors to central nervous system effects are unclear.

In addition to acute cholinergic effects, OPs cause two other toxic, non-muscarinic syndromes: intermediate syndrome (IMS) and organophosphorus-induced delayed peripheral neuropathy (OIDPN). IMS is a recurrence of weakness that occurs hours to days after a serious OP exposure [7]. Some authors have suggested that IMS is caused by inadequate oxime therapy when serum OP concentrations remain elevated because of redistribution, altered metabolism, or decreased clearance [8]. It is also possible that IMS is caused by desensitization block with downregulation and eventual decrease in the nicotinic receptor activity. As the nicotinic receptor has five subunits, there may be genetic variants that affect clinical responses [9].

The second noncholinergic syndrome is OIDPN. This is a delayed peripheral neuropathy which appears to be mediated by a membrane-bound specific “neuropathy target esterase.” OPs that have been associated with OIDPN are aryl organophosphorus esters that contain either a pentavalent phosphorus atom (type I, including derivatives of phosphoric, phosphonic, and phosphoramidic acids, or phosphorofluoridates) or a trivalent phosphorus atom (type II or phosphorus acid derivatives). This neuropathy primarily involves motor fibers. Histologic analysis shows progressive neuronal degeneration, beginning with axonal swelling followed by demyelination, axonal degeneration, and neuronal cell body death and Wallerian degeneration or “dying back” phenomenon [10].
CLINICAL MANIFESTATIONS

Excessive acetylcholine produces symptoms of muscarinic and nicotinic excess. These clinical effects are outlined in Table 109.2. One mnemonic used to describe the muscarinic toxidrome is DUMBBBELS (diarrhea, urination, miosis, bronchospasm, bronchorrhea, bradycardia, emesis, lacrimation, salivation). A mnemonic to describe the nicotinic toxidrome is Monday-Tuesday-Wednesday-Thursday-Friday (mydriasis, tachycardia, weakness, hypertension, fasciculations). Either nicotinic or muscarinic effects may predominate and can lead to misdiagnosis [11]. Miosis may be the most sensitive marker for moderate or severe exposure to an AChE inhibitor [12]. Lacrimation, rhinorrhea, salivation, and profuse sweating are common in moderate to severe poisoning. Abdominal cramping, diarrhea, and vomiting are very common with severe poisoning. Fasciculations are typically observed in severe overdoses.

Respiratory failure is a common cause of death from AChE inhibitor poisoning [2]. Cholinergic excess has direct deleterious effects on the respiratory system: it causes bronchial muscle spasm and noncardiogenic pulmonary edema with exuberant mucus production, severe respiratory muscle impairment, and centrally mediated respiratory depression. Respiratory failure may be further complicated by aspiration.

Cardiac toxicity has been increasingly described as a complication of OP poisoning. There are three phases of reported toxicity including a brief period of intense sympathomimetic tone, a period of enhanced parasympathetic activity, and corrected QT (QTc) interval prolongation with potential for torsade de pointes. Prolongation of the QTc is a marker of severity, and patients with a QTc greater than 440 ms require higher doses of atropine and have a higher mortality than those with a QTc less than 440 ms [13]. Electrocardiographic abnormalities including nonspecific ST-T changes (including ST segment elevation), tachydysrhythmias, bradydysrhythmias, and polymorphic ventricular tachycardia (torsade de pointes) have been reported [14]. Autopsy examination of OP victims has demonstrated direct myocardial injury with myocardial interstitial edema, inflammation, and vascular congestion [15]. The effect on blood pressure is variable. Patients poisoned with dimethoate have an initial benign course but develop delayed refractory hypotension and cardiogenic shock within 36 to 48 hours [2].

The CNS effects of cholinergic poisoning include altered mental status, seizures, and coma [2]. Dystonias and choreoathetoid movements have also been observed [16]. Less severe acute manifestations include anxiety, agitation, emotional lability, headaches, insomnia, tremor, difficulty in concentrating, slurred speech, ataxia, and hyperreflexia or hyporeflexia. In some cases, acute OP poisoning may produce longer lasting neuropsychiatric sequelae [17]. This has been labeled the chronic organophosphorus-induced neuropsychiatric disorder. These problems seem most severe after serious acute intoxications and usually resolve within 1 year [17].

Cholinergic signs and symptoms typically begin minutes to hours after exposure [2]. Symptom onset is rarely more than 12 hours after exposure. Onset may be delayed for lipophilic compounds (e.g., fenthion, dichlofenthion, leptophos) [2] or compounds that require hepatic metabolism to a more toxic intermediate (e.g., parathion is metabolized
to paraoxon) [18]. Dermal exposure may likewise lead to delayed systemic effects. Progressive or prolonged symptoms raise the suspicion of continued absorption of the poison and/or exposure to highly lipophilic compounds.

Life-threatening cholinergic symptoms from OP toxicity generally abate within 1 to 3 days, although many cases requiring weeks of intensive care are reported [19]. Symptoms usually resolve within 12 to 48 hours after exposure to carbamates and other reversible cholinesterase inhibitors [20].

The IMS is characterized by weakness of neck muscles, motor cranial nerves, proximal limb muscles, and respiratory muscles, but without prominent muscarinic findings. It usually begins 24 to 96 hours after the onset of poisoning and lasts 4 to 18 days. [8]. Clinical indications of this syndrome include the inability to lift one’s heads up from his/her bed and a decrease in the pulmonary vital capacity [19].

Delayed neuropathy occurs 1 to 3 weeks after the acute cholinergic crises. Patients may initially recover then show progressive signs and symptoms of OIDPN. As this is a dying back axonopathy that usually spares the neuronal cell body, the peripheral neuropathy is characterized by both paresthesias and motor dysfunction occurring first in the longest skeletal nerves with development of foot drop and a high-stepping gait. Symptoms develop slowly and can be divided into three phases: progressive, stationary, and improvement. During the progressive phase, patients have a peripheral sensory neuropathy with complaints of burning, tightness, or pain in the legs and feet. This is followed by numbness and tingling. Subsequently, motor weakness develops, with weakness and loss of peroneal innervation causing foot drop. After approximately 1 week, the paresis may ascend symmetrically into the upper extremities. The sensory loss may occur in a stocking–glove distribution, and the patient loses proprioception. With time, a positive Romberg sign and loss of lower extremity deep tendon reflexes may develop. Flaccid paralysis may occur in severe cases. During the stationary phase, paresis and motor findings cease to progress. This may occur over 3 to 12 months. The improvement phase usually begins 6 to 18 months after exposure, though improvement may be seen as early as 2 to 9 weeks. Partial or complete motor function returns in reverse order of loss. During this phase, central cord or brain lesions may be unmasked and spasticity can develop [21].
The diagnosis of the cholinergic poisoning is based on a history of exposure, clinical findings (toxidrome), and improvement after appropriate antidotal therapy. The primary laboratory studies for evaluating anticholinesterase poisoning are plasma cholinesterase (also known as butyrylcholinesterase or pseudocholinesterase) and red blood cell (RBC) AChE activity. Both may be used to confirm the clinical diagnosis. RBC AChE has a structure similar to synaptic AChE and has been validated as a surrogate for synaptic AChE [22]. These tests are not rapidly available in most hospital laboratories but portable Point of Care Testing kits with the ability to measure both plasma and erythrocyte cholinesterase are now available and are being used by the military [23].

Plasma cholinesterase is an acute phase reactant which is synthesized in the liver. It differs from RBC AChE in that it has a much more rapid response to inhibition and recovery. It is relatively insensitive to oxime therapy. Only transient decreases of RBC and plasma cholinesterase occur with carbamate poisoning because inactivated AChE spontaneously reactivates with plasma elimination half-lives of 1 to 2 hours [24].

In suspected cholinesterase inhibitor poisoning, plasma and RBC AChE levels should be sent for laboratory determination initially and repeated if the clinical course is atypical [25]. Blood for cholinesterase determination should be drawn into a fluoride-free tube as fluoride inactivates enzyme systems. Samples should be spun down and frozen for storage. The assaying laboratory should be contacted to obtain specific drawing and storing instructions.

Acute exposures are usually classified based on the degree of depression of RBC cholinesterase: mild (20% to 50% of baseline), moderate (10% to 20% of baseline), and severe (less than 10% of baseline) (see Table 109.2). An electromyography (EMG) using repetitive tetanic nerve stimulation can be done to characterize the block and to estimate the amount of enzyme inhibition [26]. As there is a wide variation in normal RBC cholinesterase level with substantial interindividual variation, a person’s baseline should be established if the person will be return to working with pesticides [27]. Workers should be removed from exposure until RBC cholinesterase is at least 75% of their baseline values [28]. Workers who do not have an established RBC cholinesterase baseline should not return to work until their RBC cholinesterase values have reached a plateau.
Several OPs are metabolized to p-nitrophenol which is easily detected in the urine soon after poisoning [29]. OP concentrations can be measured in serum [30], but contribute little to patient management. These measurements can be useful in determining residual OP residue in a patient with prolonged signs of toxicity and thus can help guide further antidotal therapy. [26]. Supplemental studies include serum electrolytes, blood urea nitrogen, creatinine, glucose, calcium, magnesium, lipase, arterial blood gases, electrocardiography, and chest radiography.

The IMS is diagnosed by clinical findings associated with a reproducible EMG-nerve conduction study using repeated submaximal tetanic nerve stimulation and measuring compound muscle action potentials [31]. No specific laboratory studies are available for evaluating OIDPN. EMG may help to determine the extent of the peripheral neuropathy, and there are specific EMG findings associated with OIDPN [32].

Toxicologic differential diagnosis for cholinergic toxicity includes poisoning with nicotine, carbachol, methacholine, arecoline, bethanechol, pilocarpine, and Inocybe or Clitocybe mushrooms. Nontoxicologic diagnoses that may be mistaken for cholinergic toxicity include myasthenia gravis, Guillain–Barré, and Eaton–Lambert syndrome.
Patients with all but the mildest symptoms should be admitted to an intensive care unit for careful observation and antidotal therapy as clinically indicated. The initial priorities are managing the patient’s airway, breathing, and circulation. All personnel who are involved in the resuscitation and decontamination process should wear masks or respirators, aprons, and nitrile or butyl rubber gloves to avoid secondary contamination.

Clinical scoring systems are used in a variety of disease processes to predict mortality. A number of systems have been applied to the context of OP poisoning including the Acute Physiology and Chronic Health Evaluation (APACHE) II, the Peradeniya Organophosphorus Poisoning (POP) scale, the International Program on Chemical Safety Poison Severity Score (IPCS PSS), the Mortality Prediction Model (MPM), the Poisoning Severity Score (PSS), the Sequential Organ Failure Assessment (SOFA), the Glasgow Coma Score (GCS), and the Simplified Acute Physiology Score (SAPS) II. Numerous studies have been performed in different countries testing the relative performance of each scale with varying results [33–35]. Regardless, the value of clinical scoring systems likely resides in their ability to define a patient population that will require transfer to a higher level of care in under-resourced countries and/or can be used for implementation of treatment guidelines.

Most patients with severe cholinergic poisoning will require airway management and ventilatory assistance for respiratory failure. Succinylcholine should be used with caution to aid intubation because prolonged (hours to days) paralysis may result [36]. A reasonable alternative is to use a rapid-onset nondepolarizing neuromuscular blocker such as rocuronium. Airway and bronchial secretions are treated with atropine. The initial adult dose of atropine is 1 to 2 mg parenterally, which is doubled every 5 minutes (pediatric dose, 0.05 mg per kg) as needed until pulmonary secretions are controlled [37].

Initial resuscitation with intravenous (IV) fluids is needed because of significant fluid losses. Blood pressure support may require direct-acting pressors such as norepinephrine, phenylephrine, and epinephrine, and cardiac depression may require the use of inotropes such as dobutamine [2]. Patients should be treated with atropine until the systolic blood pressure is greater than 80 mm Hg and urine output exceeds 0.5 mL/kg/h in addition to biochemical signs of improved perfusion [37]. Electrical pacing is rarely needed to treat ventricular dysrhythmias. Potassium and magnesium should be normalized to minimize QTc prolongation.
Seizures should be treated with IV atropine and a benzodiazepine (diazepam, 0.2 to 0.4 mg per kg or an equivalent). Animal studies suggest that both atropine and benzodiazepine are effective [38]. Given the potential benefits of benzodiazepines in severe OP poisonings to mitigate neuropsychiatric sequelae, it is reasonable to administer a benzodiazepine even if seizures are not apparent. There is no evidence to support routine use of other anticonvulsants.

Decontamination can limit absorption and prevent reexposure. All of the patient’s clothing should be removed, bagged in plastic and discarded, and the person should be thoroughly washed with mild soap and water. Dilute hypochlorite solution (household bleach) inactivates the organophosphorus ester and can be used to decontaminate equipment but should not be used on skin [39]. If an ingestion is recent, nasogastric suction can used to attempt to aspirate any product remaining in the stomach [40]. Although single and multidose charcoal did not change outcome in one trial [41], many of the subjects in this trial had long delays before treatment and it is possible that earlier treatment may limit toxicity.

Antimuscarinic antagonism is the mainstay of initial antidotal therapy. In fact, rapidly incremental atropine dosing regimens have demonstrated improvements in mortality [42]. Atropine is a competitive antagonist of acetylcholine at the muscarinic receptors but has no effect at the neuromuscular junction, so muscle weakness and paralysis are not affected and it does not affect the AChE regeneration rate. As noted previously, atropine is primarily indicated for control of pulmonary secretions and bronchospasm. It has a secondary role in helping to control seizures and CNS manifestations of poisoning [43]. A continuous atropine infusion may be necessary to stabilize the patient, after which the infusion can be titrated back under close observation. In a large Sri Lankan case series, most patients responded to 3 to 5 mg per hour [40]. In general, higher doses of atropine are required during the first 24 hours with OP pesticides than with nerve agents. Tachycardia is not a contraindication to atropine therapy and may reflect hypoxia or sympathetic stimulation. Mydriasis is an early response but is a poor marker for adequate atropinization. A common pitfall is inadequate atropine dosing during serious cholinergic agent overdoses. High doses of atropine are commonly needed for control of secretions. Daily doses in excess of 100 mg are occasionally required for several days [44]. Frequent clinical evaluation and reevaluation is necessary when titrating atropine to prevent atropine toxicity [40,42].

Glycopyrrolate is an antimuscarinic agent that does not penetrate the CNS and is unlikely to be effective in treating CNS effects such as seizures or coma. It can be substituted for atropine when isolated peripheral cholinergic toxicity is present. The recommended starting dose is 0.05 mg...
per kg. One study suggested that a combination of atropine and glycopyrrolate may improve outcomes [45]. Likewise, ipratropium may be considered for continued pulmonary secretions, although limited evidence exists.

Antidotal therapy with oximes such as pralidoxime (North America, India, and Asia) or obidoxime (Europe and Middle East) is considered a mainstay of treatment but is lacking robust evidence demonstrating improved outcome. Pralidoxime (2-PAM) and obidoxime are nucleophilic oximes that regenerate AChE at muscarinic and nicotinic synapses by reversing the AChE active site phosphorylation. Although pralidoxime does not enter the CNS well, rapid improvement in coma or termination of seizures has been observed after pralidoxime administration [46]. The antidotal effect of atropine and oximes is synergistic.

Although oximes remain a standard therapy for OP poisoning, recent studies have highlighted our limited understanding of their role. Available data are conflicting; one recent randomized controlled trial showed a dramatic treatment effect with pralidoxime [47], whereas a second trial found no benefit and a trend toward worse outcomes [48]. The most recent Cochrane review concluded “current evidence was insufficient to indicate whether oximes are harmful or beneficial” [49]. A more recent retrospective study found an association between mortality and the combination of delay in oxime administration, severity of poisoning, and duration of mechanical ventilation [50]. Another recent retrospective observational study found the use of “high-dose pralidoxime” was associated with decreased mortality (13% to 1.9%) [51].

There are several possible explanations for these discrepant results including differences in the OP lipophilicity, side chains (O’-dimethyl vs. O’-diethyl OPs), rate of aging, and interaction between inhibition/re-inhibition and spontaneous reactivation of the parent OP and oxime-bound compounds. Future studies will have to address these differences.

Although the optimal treatment protocol for pralidoxime is not known, there is consensus that many older protocols used insufficient doses [52]. Although earlier animal studies suggested maintaining a serum concentration of 4 mg/L [53], obtained by 1 to 2 g IV pralidoxime followed by 1 g every 6 to 12 hours [54,55], subsequent studies in poisoned patients have shown that the amount of circulating inhibitor (parent or metabolite of the original OP) actually determines the need for oxime dose [56]. Patients who have ingested massive amounts of an OP may have prolonged high levels of circulating inhibitor lasting for days after ingestion, and the pralidoxime blood level of 4 mg/L is too low to
reactivate the AChE. Ideally, poisoned patients should be followed by serial evaluation of the ability to reactivate their cholinesterase in vitro [6]. As this is not feasible for most patients, the following suggestions can be made. The World Health Organization recommends an initial pralidoxime dose of 30 mg per kg IV followed by 8 mg/kg/h or alternatively, 30 mg per kg every 4 hours if a continuous infusion is not possible [52]. The appropriate dose of obidoxime 250 mg is initially followed by 750 mg over 24 hours [57]. In both cases, the dose is adjusted to effect. Muscle fasciculations and weakness should show a response within 60 minutes after dosing; the dose should be increased if the patient has breakthrough signs and symptoms. In mass casualty situations, the intramuscular route of administration may be more practical. The duration of therapy is based on clinical response and is usually 24 to 48 hours. Under ideal conditions, serum samples can be assayed for AChE reactivation and this can be used to guide oxime therapy [58]. Some patients may require continuous treatment for greater than 1 week, depending on the body burden and fat solubility of OP, and re-inhibition of reactivated AChE.

Although hemoperfusion can enhance the elimination of anticholinesterase agents [59], the availability of specific antidotes for OPs and the relatively short course of carbamate intoxications make this procedure unnecessary. There are no outcome studies using hemoperfusion.

Alternative therapies are under investigation. Administration of an enzyme that can scavenge, hydrolyze, and inactivate circulating OP has great theoretical appeal. Such hydrolases have been found in both bacteria and humans and are generically termed “OP hydrolases” [60]. These hydrolases can be genetically engineered to inactivate a wide variety of organophosphorus compounds [61]. Pretreatment studies in animals with hydrolases confer protection against various OPs, including nerve agents [62–65]. Data from animal studies, including nonhuman primates, show promise as rescue therapy [66–68]. It is unclear whether there will be a continued push toward clinical development.

Although other therapies including sodium bicarbonate [69], magnesium sulfate [70], β adrenergic agonists, and lipid emulsion therapies [71] have shown some promise, a lack of larger, randomized controlled trials in humans prevents them from being routinely recommended.

In general, carbamate poisonings have a good prognosis because the duration of serious signs and symptoms is limited. Severe OP poisonings may require prolonged respiratory support, with its attendant complications. Death from acute OP poisonings usually occurs within 24 hours in untreated cases. It should be noted that exposures to fenthion and dimethoate may be delayed beyond 72 hours even if treated [2].
Aggressive respiratory management, timely antidotal therapy, and intensive supportive care are expected to improve morbidity and mortality. Recovery from OIDPN may be gradual or not at all. CNS anoxic sequelae have the worse prognosis and are not specific to cholinesterase inhibitors but rather a consequence of prolonged hypoxia.

**Toxicity of Acetylcholinesterase Inhibitors Used to Treat Alzheimer’s Disease**

With the increasing use of AChE inhibitors to treat dementia, there has been an increasing number of exposures to these medications. Symptoms can range from general weakness [72] to salivation and gastrointestinal effects [73] but are generally milder than pesticides. One case of deliberate ingestion of 288 mg of rivastigmine resulted in seizures, respiratory muscle weakness, and bronchial secretions [74]. Muscarinic effects should be treated with atropine and one report has suggested that isolated CNS effects without peripheral muscarinic symptoms can be treated with pralidoxime alone [75].
NERVE AGENTS USED IN WARFARE

Since the Persian Gulf War and in the aftermath of the terrorist attacks of September 11, 2001, there has been increasing concern about the potential use of G-series (GA [Tabun], GB [Sarin], GD [Soman]) V-series (VE, VG, VM, VX), and the Russian “Novichok” nerve agents. These chemicals are similar in structure and function to the OP insecticides but have a much greater potency. Please see Chapter 128 for a complete discussion of this topic.

Cocaine Poisoning

Cocaine (benzoylmethylecgonine) is an alkaloid compound derived from the South American plant *Erythroxylon coca*. Its use as an illicit drug of abuse has reached epidemic proportions. Thirty-four million US citizens have used cocaine at least once; 5.9 million have used cocaine in the past year; and 2.1 million have used cocaine in the past month [1]. Other than alcohol, cocaine is the most common cause of acute drug-related emergency department visits, accounting for 31% of all visits to the emergency department related to drug misuse or abuse [2].

PHARMACOLOGY

The pharmacologic effects of cocaine are complex, and they include direct blockade of the fast sodium channels, increase in norepinephrine release for the adrenergic nerve terminals, interference with neuronal catecholamine reuptake, and increase in excitatory amino acid concentration in the central nervous system (CNS). Blockade of the fast sodium channels stabilizes axonal membranes, producing a local anesthetic-like effect and a type I antidysrhythmic effect on the myocardium. The increase in catecholamine levels produces a sympathomimetic effect. The result of increased excitatory amino acid concentration in the CNS is increased extracellular dopamine concentration.

Cocaine is well absorbed through the mucosa of the respiratory, gastrointestinal, and genitourinary tracts, including less common routes of absorption such as the urethra, bladder, and vagina. The cocaine hydrochloride salt is the form most often abused nasally or parenterally. Crack cocaine and cocaine freebase are alkaloid forms of cocaine that are produced by an extraction process. These forms are heat stable, can be
smoked, and are absorbed through the pulmonary system. When intravenously administered or inhaled, cocaine is rapidly distributed throughout the body and CNS, with peak effects in 3 to 5 minutes. With nasal insufflation, absorption peaks in 20 minutes.

Cocaine has a half-life of 0.5 to 1.5 hours. It is rapidly hydrolyzed to the inactive metabolites eegonine methyl ester and benzoylecgonine, which account for 80% of cocaine metabolism. These compounds have half-lives of 4 to 8 hours and have some cardiovascular effects that are similar to the parent compound. Minor cocaine metabolites include eegonine and norcocaine. Urinary toxicology screens for recreational drugs typically assess for the presence of benzoylecgonine, which is usually present for 48 to 72 hours after cocaine use [3].

Cocaine is frequently abused in combination with other drugs, particularly ethanol. This may be a popular combination because ethanol antagonizes the stimulatory effects of cocaine. The metabolism of cocaine in the presence of ethanol produces cocaethylene, which has additional cardiovascular and behavioral effects [4]. Cocaethylene and cocaine are similar with regard to behavioral effects. However, cocaethylene has been more likely to result in death in animal studies. Human studies demonstrate that cocaethylene produces milder subjective effects and similar hemodynamic effects when compared with cocaine. Cocaethylene also has a direct myocardial depressant effect [4,5].

Cocaine toxicity is due to an exaggeration of its pharmacologic effects, resulting in myriad consequences that have an impact on every organ system. The widespread effects of cocaine are related to its ability to stimulate the peripheral and central sympathetic nervous systems, in addition to local anesthetic-like effects. Cocaine-induced seizures are most likely due to excess catecholamine stimulation.

Cocaine causes vascular effects through multiple pathophysiologic mechanisms that have been best described in the heart [6–8]. These include arterial vasoconstriction, in situ thrombus formation, platelet activation, and inhibition of endogenous fibrinolysis. In addition, myocardial oxygen demand is increased by cocaine-induced tachycardia and hypertension [6–9]. The direct local anesthetic-like effect of cocaine or secondary cocaine-induced myocardial ischemia [6,10] may be responsible for cardiac conduction disturbances [10] and dysrhythmias.
Clinical manifestations of acute cocaine toxicity may occur in a number of different organ systems. Most severe cocaine-related toxicity and cocaine-related deaths are manifested by signs of sympathomimetic overdrive (e.g., tachycardia, hypertension, dilated pupils, and increased psychomotor activity). This increased psychomotor activity causes increased heat production and can lead to severe hyperthermia and rhabdomyolysis [11].

Cocaine-induced cardiovascular effects are common. Of cocaine-related emergency department visits, chest pain is the most common complaint. Although most of the patients do not have serious underlying etiology, myocardial infarction due to cocaine is a well-established entity and needs to be excluded [12,13]. It occurs in 6% of patients presenting with cocaine-associated chest pain [14]. The risk of myocardial infarction is increased 24-fold in the hour after cocaine use. In patients aged 18 to 45 years, 25% of myocardial infarctions is attributed to cocaine use [15]. Cocaine-associated myocardial infarction typically occurs in patients aged 18 to 60 years without apparent massive cocaine exposure or without evidence of cocaine toxicity. Patients with cocaine-associated myocardial infarctions frequently have atypical chest pain or chest pain that is delayed hours to days after their most recent cocaine use [6,12].

Cardiac conduction disturbances (e.g., prolonged QRS and QTc) and cardiac dysrhythmias (e.g., sinus tachycardia, atrial fibrillation/flutter, supraventricular tachycardias, idioventricular rhythms, ventricular tachycardia, torsade de pointes, and ventricular fibrillation) may occur after cocaine use [16–18]. Aortic dissection and endocarditis associated with cocaine abuse are uncommon [19].

The neurologic effects of cocaine may be manifested in a number of ways. Altered mental status and euphoria are typically short lived and without serious sequelae. The stimulatory effects of cocaine can lead to seizures, cerebral infarction, intracerebral bleeding, subarachnoid hemorrhage, transient ischemic attacks, migraine-type headache syndromes, cerebral vasculitis, anterior spinal artery syndrome, and psychiatric manifestations [20–24,24a]. Cocaine is associated with a sevenfold increased risk of stroke in women [23].

Cocaine-induced seizures are typically single, brief, generalized, self-limited, and not associated with permanent neurologic deficit [24,24a]. These seizures may occur in the presence or absence of concurrent structural disease, such as infarction or hemorrhage. Multiple or focal seizures are usually associated with concomitant drug use or an underlying seizure disorder [20].
Cocaine has a number of direct and indirect effects on the lungs, and they are associated with how the drug is used [25]. These effects include asthma exacerbations, pneumothorax, pneumomediastinum, noncardiogenic pulmonary edema, alveolar hemorrhage, pulmonary infarction, pulmonary artery hypertrophy, and acute respiratory failure [26,27]. Asthma exacerbations are more common with crack cocaine usage, most likely due to particulate by-products of combustion [27]. Inhalation of cocaine is typically associated with deep Valsalva maneuvers to maximize drug delivery and can cause pneumothorax, pneumomediastinum, and noncardiogenic pulmonary edema.

The intestinal vascular system is particularly sensitive to cocaine effects because the intestinal walls have a wide distribution of $\alpha$-adrenergic receptors. Acute intestinal infarction has been associated with all routes of cocaine administration [28].

The most deadly gastrointestinal manifestation of cocaine usage is seen in the patient who presents after ingesting packets filled with cocaine. These patients have been termed body packers or body stuffers. Body packers are patients who swallow carefully prepared condom or latex packets filled with large quantities of highly purified cocaine for the purposes of smuggling this drug into the country. In contrast, body stuffers are typically “street” drug dealers who swallow packets of cocaine while fleeing the police. These packets are generally prepared for distribution to individual customers and not to protect the body stuffer from absorbing cocaine. It was previously thought that cocaine ingested orally was metabolized in the gastrointestinal track and did not lead to systemic toxicity. This is clearly not the case and toxicity can develop in body stuffers and packers from cocaine leaking out of the swallowed packets. The dosage of cocaine exposure in body stuffers is generally substantially less than that of a body packer. However, toxicity is more likely to occur in the setting of body stuffers. Although massive exposure to leakage from a condom or latex-filled packet of a body packer can occur, most body packers identified by airport immigration officers do not develop clinical toxicity. However, any patient identified as a body packer who has developed any signs of systemic cocaine toxicity (tachycardia, hypertension, diaphoresis, etc.) can rapidly develop worsening symptoms including life-threatening ones. These patients, when identified, have a high potential for progressively worsening toxicity and mortality [29].

Premature atherosclerosis may develop in some chronic cocaine users. Further, cocaine-induced left ventricular dysfunction can lead to
hypertrophy and eventually a dilated cardiomyopathy and congestive heart failure [6]. Cocaine-associated dilated cardiomyopathy appears to have a reversible component, and some patients have demonstrated improvement after cessation of cocaine use [6].

Chronic severe cocaine users can present with lethargy and a depressed mental status that is not attributable to any other etiology (diagnosis of exclusion), the “cocaine washout syndrome.” This self-limited syndrome usually abates within 24 hours but can last for several days and is thought to result from excessive cocaine usage that depletes essential neurotransmitters [30].

Chronic inhalational use of cocaine does not appear to lead to long-term pulmonary effects. Spirometry and lung mechanics are typically normal even in heavy chronic users [31].

Chronic cocaine usage during pregnancy increases the chance of premature delivery and abruptio placentae [32]. Maternal cocaine usage is associated with low birth weight, small head circumference, developmental problems, and birth defects in the neonate [33–35]. Neonates exposed to cocaine in utero may develop cocaine withdrawal syndrome, which typically begins 24 to 48 hours after birth and is characterized by irritability, jitteriness, and poor eye contact.

In recent years, there has been an increased number of cases in which levamisole, an anthelmintic and immunomodulator, has been found as an adulterant in street cocaine. Although issues associated with levamisole are not directly caused by cocaine, the frequency with which levamisole is found as an adulterant makes this discussion relevant to cocaine toxicity. In addition, levamisole was withdrawn from the United States market by the FDA in 1999 due to concerns regarding agranulocytosis. In association with cocaine, levamisole has not only been implicated in cases of agranulocytosis, but has had multiple reports of cutaneous vasculitis. The purpose of adulterating street cocaine with levamisole is not known, but it is speculated to potentiate the effects of cocaine [36,37].
DIAGNOSTIC EVALUATION

Patients manifesting cocaine toxicity should have a complete evaluation focusing on the history of cocaine use, signs and symptoms of sympathetic nervous system excess, and evaluation of specific organ system complaints. It is of paramount importance to determine whether signs and symptoms are due to cocaine itself, underlying medical conditions, or cocaine-induced exacerbation of medical conditions.

When the history is clear and symptoms are mild, laboratory evaluation is usually unnecessary. In contrast, if the patient manifests moderate or severe toxicity, routine laboratory evaluation may include a complete blood cell count, serum electrolytes, glucose, blood urea nitrogen, creatinine, creatine kinase (CK), cardiac marker determinations, arterial blood gas analysis, electrocardiogram, and urinalysis. Sympathetic excess may result in hyperglycemia and hypokalemia. Elevated CK is associated with rhabdomyolysis. Cardiac markers are elevated in myocardial infarction. However, false elevations of CK–MB fraction are common [13]. Cardiac troponin is the preferred method to diagnose myocardial injury in cocaine users [13]. Urine drug testing may be helpful in establishing recent cocaine use.

Chest radiography and electrocardiography (ECG) should be obtained in patients with chest pain or cardiovascular complaints. The initial ECG is a less useful diagnostic tool than for patients with chest pain that is unrelated to cocaine. Many young cocaine-using patients have ST-segment elevation in the absence of acute myocardial infarction. This is due to early repolarization changes [16,17].

Observation for a 9- to 12-hour period is also a useful tool for the evaluation of patients presenting with cocaine-associated chest pain. Patients without new ischemic changes on ECG, a normal troponin test, and no cardiovascular complications during this observation (dysrhythmias, acute myocardial infarction, or recurrent symptoms) can safely be sent home with follow-up and planned outpatient workup [18,38]. The use of coronary computerized angiographic tomography might identify patients safe for discharge in a slightly more rapid time frame [39].

A brief seizure temporally related to cocaine use in an otherwise healthy person should be evaluated with a head computed tomography (CT). Further workup in an otherwise asymptomatic patient may not be necessary [20,24,24a]. Patients with concurrent headache, suspected subarachnoid hemorrhage, or other neurologic manifestations may necessitate lumbar puncture after head CT to rule out serious pathology. Patients who are suspected of body stuffing should be evaluated by
abdominal radiographs and cavity searches (digital or visual examination of the rectum or vagina).
The initial management of cocaine-toxic patients should focus on airway, breathing, and circulation. Treatments are directed at a specific sign, symptom, or organ system affected and are summarized in Table 110.1.

Patients who present with sympathetic excess and psychomotor agitation are at risk of hyperthermia and rhabdomyolysis. Management should focus on lowering core body temperature, halting further muscle damage and heat production, and ensuring good urinary output. The primary agents used for muscle relaxation are benzodiazepines [12].

The use of antipsychotic agents for cocaine-induced neurobehavioral agitation is controversial [40]. In mild cases, antipsychotics may be useful. In cases of severe cocaine-induced agitation, few data exist on the safety and efficacy of antipsychotics. In these cases, benzodiazepines are preferred and supranormal cumulative doses may be necessary. Core body temperatures may be highly elevated. This should be treated aggressively with surface cooling devices. Some cases of severe muscle overactivity may require general anesthesia with nondepolarizing neuromuscular blockade. Succinylcholine, a depolarizing neuromuscular-blocking agent, may increase the risk of hyperkalemia in the setting of severe cocaine-induced rhabdomyolysis and should be avoided. In addition, plasma cholinesterase is responsible for the metabolism of both succinylcholine and cocaine. When these two agents are used
simultaneously, prolonged clinical effects of either or both agents might result. Therefore, nondepolarizing agents are preferred.

Patients with severe hypertension can usually be safely treated with benzodiazepines. When benzodiazepines are not effective, nitroglycerin, nitroprusside, or phentolamine can be used. β-Blockers are contraindicated. Their use in this setting can lead to unopposed alpha stimulation with paradoxic exacerbation of hypertension and worsening coronary vasoconstriction [41].

Patients with chest pain and suspected cocaine-induced ischemia or myocardial infarction should be treated with aspirin, benzodiazepines, and nitroglycerin as first-line agents. Benzodiazepines decrease the central stimulatory effects of cocaine, thereby indirectly reducing its cardiovascular toxicity [12]. Benzodiazepines have been shown to have a comparable and possibly an additive effect to nitroglycerin with respect to chest pain resolution and hemodynamic and cardiac functional parameters (cardiac output) for patients with cocaine-associated chest pain [42,43] (Table 110.2). Weight-adjusted unfractionated heparin or enoxaparin would be reasonable to use in patients with documented ischemia. Patients who do not respond to these initial therapies can be treated with phentolamine or calcium channel blocking agents [44,45]. The International Guidelines for Emergency Cardiovascular Care recommend α-adrenergic antagonists (phentolamine) for the treatment of cocaine-associated acute coronary syndrome [46]. β-Blockers are contraindicated, as they can exacerbate cocaine-induced coronary artery vasoconstriction [41]. However, this recommendation has come under some scrutiny. Recent studies suggest that β-blocker usage in the setting of cocaine toxicity does not appear to obviously increase detrimental clinical outcomes [47,48]; however, the relatively low mortality associated with myocardial infarction due to the documented adverse effects of cocaine has resulted in the American College of Cardiology/American Health Association guidelines continuing to recommend against its use in cases of acute intoxication [13].

coronary syndrome, diazepam (N = 13), or diazepam and nitroglycerin arms were used (N = 15). Diazepam was administered 5 mg intravenously every 5 min for a total dose of 15 mg. Nitroglycerin, 0.4 mg, was administered sublingually every 5 min for up to a total of 3 doses.

[43] 27 patients with cocaine-associated chest pain
Nitroglycerin (group I, N = 15) or nitroglycerin plus lorazepam (group II, N = 12) was utilized. The nitroglycerin was administered sublingually and the lorazepam was administered intravenously, 1 mg every 5 min. No patients received placebo. Chest pain score (0–10 scale) measured at 5 min after each medication administration. Prospective, randomized, single-blind trial.
Primary reperfusion therapy is best done with percutaneous interventions, when available [49]. Fibrinolytic therapy in this setting is somewhat controversial. The mortality from cocaine-associated myocardial infarction is low. Patients with cocaine-associated chest pain have a high prevalence of “false-positive ST-segment elevations,” up to 43% in one study [50]. Therefore, treatment of all patients with cocaine-associated chest pain who meet standard ECG thrombolysis in myocardial infarction criteria would result in fibrinolytic administration to more patients without acute myocardial infarction than with acute myocardial infarction.

Supraventricular dysrhythmias may be difficult to treat. Initially, benzodiazepines should be administered. Adenosine can be given, but its effects may be temporary. Use of calcium channel blockers in association with benzodiazepines appears to be most beneficial. β-Blockers should be avoided [41].

Ventricular dysrhythmias should be managed with benzodiazepines, lidocaine, or sodium bicarbonate [46]. Bicarbonate is preferred in patients with QRS widening and ventricular dysrhythmias that occur soon after cocaine use. In this setting, the dysrhythmias are presumably related to the sodium channel blocking effects of cocaine. Lidocaine or amiodarone can be used when dysrhythmias appear to be related to cocaine-induced ischemia [10,46].

Seizures should be treated with benzodiazepines and, phenobarbital or propofol. Phenytoin is not recommended in cases associated with cocaine. Although no studies have compared barbiturates to phenytoin or propofol for control of cocaine-induced seizures, barbiturates are theoretically preferable because they also produce CNS sedation and are generally more effective for toxin-induced convulsions. If these agents are not rapidly effective, nondepolarizing neuromuscular blockade and general anesthesia are indicated.

Patients with cerebrovascular complications or focal neurologic findings should be managed as usual. However, the utility of fibrinolytic agents in cocaine-associated cerebrovascular infarction is unknown.

Cocaine body stuffers who are asymptomatic should be given activated charcoal [51]. Whole-bowel irrigation with subsequent radiologic
verification of passage of all drug-filled containers should be considered [29]. Body stuffers who manifest clinical signs of toxicity should be treated similar to other cocaine-intoxicated patients. Body packers who develop any signs of cocaine toxicity need to be identified as quickly as possible and treated very aggressively. These individuals have a high likelihood of developing worsening toxicity and life-threatening symptomatology. Initial use of activated charcoal and surgical removal of ruptured cocaine packets is warranted in almost all cases and can be life saving [29].

Initially referring to acids, the term *corrosives* is now used synonymously with *caustics*, a term originally applied to alkalis. In solution, acids and bases donate or accept a proton altering the hydrogen ion concentration. This is measured as pH, the negative logarithm of the $H^+$ ion concentration (mol/L). Water, at 25°C, has a pH of 7 and is considered neutral. Solutions with a pH of less than 2 or greater than 12 are considered strongly acidic or basic, respectively. The pH values of some common solutions are listed in Table 111.1.

Corrosives cause injury by reacting with organic molecules and disrupting cell membranes. They also cause thermal burns from the heat generated by dissolution and neutralization reactions. Reactions between strong acids and strong bases are usually highly exothermic. Metallic lithium, sodium, potassium, some aluminum and lithium salts, and titanium tetrachloride react violently when placed in water, producing large amounts of heat. Chlorine reacts with water in an exothermic reaction to form hydrochloric and hypochlorous acids, elemental chlorine, and free oxygen radicals. Similar reactions occur with bromine. Ammonia combines with water to form ammonium hydroxide in a reaction that liberates heat; the hydroxide formed is then responsible for the corrosive effects. Nitrogen dioxide reacts with water to release heat and produce nitric and nitrous acid. Hydrogen peroxide liberates oxygen on contact with water.

The mixing of chemicals can result in reactions that liberate caustic gases. Mixing ammonia with hypochlorite (household bleach) generates chloramine gases (NH$_2$Cl and NHCl$_2$), which are highly irritating to mucosal epithelia. Combining bleach with acid (acid toilet bowl or drain cleaners) produces chlorine gas. A number of metallic compounds react with acids, resulting in the liberation of potentially explosive hydrogen gas. The potential for unrecognized corrosives production can complicate the identification of the exposures, and diagnosis of caustic burn may need to be based on clinical presentation rather than on product identification.

During 2014, approximately 70,000 exposures to corrosive chemicals were reported to U.S. poison centers; actual exposures are estimated to be several times greater [1]. Although pediatric exposures are more common than adult exposures, adults often ingest larger amounts of corrosive [2]. Deaths most commonly result from intentional exposure to drain cleaners and acidic cleaners [1].

Concentrated lye (sodium or potassium hydroxide) solutions used for laundering and plumbing purposes caused most of the serious injuries
due to corrosive ingestions before 1970 [2,3]. Currently available liquid lye drain cleaners are less concentrated (less than 10%) but are still responsible for the largest number of severe gastrointestinal injuries; however, acid bowl cleaners now account for almost as many deaths [1]. Severe alkali injuries can result from the ingestion of powdered automatic dishwasher detergents and oven cleaners [4]. Household ammonia and bleaches, and hydrogen peroxide solutions are, in general, much less potent than industrial ones but can cause significant injury if ingested in large amounts [4].

**PATHOPHYSIOLOGY**

Alkalis cause liquefaction necrosis, a process resulting from the saponification of fats, dissolution of proteins, and emulsification of lipid membranes. The resultant tissue softening and sloughing may allow the alkali to penetrate to deeper levels. Tissue injury progresses rapidly over the first few minutes but can continue for several hours [5]. Over the ensuing 4 days, bacterial infection and inflammation cause additional injury. Granulation tissue then develops, but collagen deposition may not begin until the second week. The tensile strength of healing tissue is lowest during the first 2 weeks. Epithelial repair may take weeks to months. Scar retraction begins in the 3rd week and continues for months.

Acid burns are characterized by coagulation necrosis. Protein is denatured, resulting in the formation of a firm eschar [6]. The release of heat is typically higher than for alkali reactions. Subsequent responses are similar to those seen with alkalis.

Hydrocarbons can produce injury by dissolving lipids in cell membranes and coagulating proteins. Significant damage may occur with ingestion or after prolonged dermal contact [7].

Alkaline solutions with a pH of greater than 12.5 are likely to cause mucosal ulceration, with deeper tissue necrosis resulting if the pH approaches 14 [8]. However, solutions with a pH of less than 12.5 can still cause significant injury, and solutions of different chemicals but the same pH produce different degrees of tissue damage [8].

The physical state of a chemical also influences its toxicity. Corrosives that are gases at room temperature primarily affect the skin, eyes, and airways. Saturated acid solutions may liberate significant amounts of acid fumes, particularly if heated. Solid compounds tend to produce highly concentrated solutions on contact with body fluids and cause more severe injuries [9]. Solutions with a high viscosity tend to cause deeper burns [8].
Most systemic effects that occur after exposure to corrosives are secondary to inflammation, acidosis, infection, and necrosis [10]. Fluid and electrolyte shifts occur, resulting in hypovolemia, acidosis, and organ failure. Some chemicals, such as phenol, hydrazine, and chromic acid, can be absorbed after dermal exposure or ingestion and cause systemic toxicity [11].
CLINICAL MANIFESTATIONS

Chemical burns to the eye range from irritation to severe and permanent damage [12]. Eye pain, blepharospasm, conjunctival hemorrhages, and chemosis are seen in all grades of injury. Decreased visual acuity may result from excessive tearing, corneal edema and ulceration, anterior chamber clouding, or lens opacities. Roper-Hall’s classification of injury predicts severity of subsequent vision loss [13] (Table 111.2). Severe burns can result in increased intraocular pressure, anterior chamber clouding, lens opacities, and perforation of the globe [12]. Severity can be assessed by the extent of ischemia of conjunctival vessels at the limbus of the eye. If more than half of these vessels are obliterated, the prognosis is poor [13].

Significant differences exist between thermal and chemical burns of the skin. Although pain usually occurs immediately, it may be delayed several hours after corrosive exposure [14]. Assessing the depth of dermal injury can be difficult. Chemical burns rarely blister, and the affected skin is usually dark, insensate, and firmly attached regardless of the burn depth [15]. Healing usually takes longer than for thermal burns.

Some chemical warfare agents cause severe dermal injury. Sulfur mustard, the most commonly used antipersonnel agent, and lewisite (chlorovinylarsine dichloride) are potent alkylating agents, resulting in severe vesiculation of the skin 4 to 12 hours after exposure. Phosgene oxide has a similar action, but its effects are almost immediate. Respiratory burns are nearly always associated with sulfur mustard exposure [16]. White phosphorus is used in incendiary devices and in the manufacture of fertilizers and insecticides. It ignites spontaneously when exposed to air and can cause thermal burns.
Ingested corrosives typically injure the oropharynx, esophagus, and stomach but may cause damage as distal as the proximal jejunum [17,18]. Areas most commonly affected are those of anatomic narrowing: the cricopharyngeal area, diaphragmatic esophagus, and antrum and pylorus of the stomach [17]. Multiple sites are affected in up to 80% of patients [18]. Esophageal lesions are seen predominantly in the lower half, and gastric burns are usually most severe in the antrum [18]. Vomiting is associated with a higher incidence of severe esophageal injuries [19].

Ingestion of alkali is associated with a higher incidence and severity of esophageal lesions than ingestion of acid, which typically causes stomach injury although this is not a consistent finding [2,19]. Alkaline agents have little taste, but acids are extremely bitter and more likely to be expelled if accidentally ingested.

Alkaline solids may adhere to mucosa of the oropharynx and cause oral pain that limits the quantity swallowed, thus sparing the esophagus [20]. If alkaline solids are swallowed, severe upper esophageal burns are seen [21]. Shallow ulcers may result when tablets become lodged in the esophagus (pill esophagitis). Hemorrhage and stricture formation may occur after esophageal impaction of potassium chloride, iron, quinidine, etidronate, antibiotics, and anti-inflammatory agents [22].

Common symptoms from corrosive ingestion are oropharyngeal pain, dysphagia, abdominal pain, vomiting, and drooling [23]. Less commonly, stridor, hoarseness, hematemesis, and melena are seen. Patients who are asymptomatic are unlikely to have significant injuries, although this may be difficult to assess for children who may appear to have no or minimal symptoms [23]. Vomiting, drooling, and stridor appear to be predictive of more severe injuries [23], but the absence of burns in the oropharynx does not exclude burns further along the gastrointestinal tract, and it is not predictive of less severe distal injuries [23]. Patients with laryngeal burns have a greater incidence and severity of esophageal lesions [19].

Hemorrhage, perforation, and fistula formation may occur for patients with full-thickness esophageal necrosis [18]. Untreated, perforations rapidly progress to septic shock, organ failure, and death. Gastric perforations may become walled to form abscesses around the liver or in the lesser sac. Severe gastric burns may extend to adjacent organs [24]. Perforation of the anterior esophageal wall may lead to formation of a tracheoesophageal fistula and tracheobronchial necrosis [25]. Tracheoesophageal–aortic and aortoesophageal fistulas, rare and uniformly fatal complications, are suggested by hemoptysis or hematemesis, which develops into torrential bleeding.

Burns to the larynx occur in up to 50% of patients and are the most common cause of respiratory distress [19]. Typically, the epiglottis and aryepiglottic folds are edematous, ulcerated, or necrotic. The absence of respiratory symptoms on presentation does not exclude the presence of
laryngeal burns that may eventually require intubation [19]. Respiratory distress may also be caused by the aspiration of corrosives [26].

Esophageal strictures develop in up to 70% of burns that result in deep ulceration, whether discrete or circumferential, and nearly all burns resulting in deep necrosis [18]. Strictures do not develop after superficial mucosal ulceration [26]. Strictures may become symptomatic as early as the end of the 2nd week; half develop during initial hospitalization, and 80% are evident within 2 months [27]. Those that develop early often progress rapidly and require urgent intervention. Gastric outlet strictures may also occur, but only 40% become symptomatic [18]. Strictures can develop in the mouth and pharynx [19]. Esophageal pseudodiverticulum may occur in patients with esophageal stricture as early as 1 week after corrosive ingestions. It appears to result from incomplete destruction of the esophageal wall and usually resolves with dilation of associated strictures [28].

Deaths that occur are in patients who have extensive necrosis in the upper gastrointestinal tract. Sepsis secondary to perforation is the most common cause of death; severe hemorrhage or aspiration may also contribute [18].

Esophageal carcinoma, usually squamous cell, is a well-documented complication of alkali burns [29]. It occurs most commonly at the level of the tracheal bifurcation and is estimated to occur 1,000 times more frequently in patients who have had corrosive injuries than in the general population. Symptoms can develop more than 20 years after the initial insult.

Systemic toxicity has occurred with burns caused by arsenic and other heavy metals, cyanide, acetic acid, formic acid, fluoride, hydrazine, hydrochloric acid, nitrates, sulfuric acid, and phosphoric acid [11,30–34]. Severe acid burns may be accompanied by a metabolic acidosis and hypotension. The anion gap is usually elevated, although a hyperchloremic acidosis may be seen in hydrochloric acid and ammonium chloride ingestion. After hydrochloric acid ingestion, cardiovascular collapse is the most common cause of early death; myocardial infarction has occurred after large ingestions. Other findings associated with severe acid injuries include hemolysis, hemoglobinuria, nephrotoxicity, and pulmonary edema [31,32]. Vascular oxygen embolization can occur after the ingestion of concentrated hydrogen peroxide [35].
DIAGNOSTIC EVALUATION

Resuscitation and decontamination should take priority over completing a detailed history and physical examination. Medical staff should wear protective clothing to avoid becoming secondary casualties. The duration of exposure, symptoms, and details of prehospital treatment should be noted. Identification of the compounds involved and any measures required for their safe handling can be established by a number of means: Container labeling, material safety data sheets and safety officers in cases of workplace exposure, fire department hazardous materials units, and regional poison information centers. Measuring the pH of a product may be helpful.

If the exposure is the result of an industrial or transportation accident, the patient should be evaluated for traumatic injuries. Suicidal patients should be evaluated for other possible toxic exposures (e.g., ingestion of alcohol or medications).

After decontamination, assessment of eye exposures should include measurement of visual acuity and conjunctival pH and a slit-lamp examination. Chemosis, conjunctival hemorrhages, corneal epithelial defects, stromal opacification, and loss of limbic vessels should be noted. If injury to the anterior chamber is suspected, intraocular pressure should be measured.

Assessment of dermal injury is similar to that for thermal burns. Location, size, color, texture, and neurovascular status should be noted. If the affected area is greater than 15% of total body surface area or if systemic toxicity is possible, a complete physical examination with appropriate monitoring and laboratory testing should be performed.

With ingestions, the ability to swallow secretions and findings on examination of the oropharynx, neck, chest, and abdomen should be noted. Particular attention should be given to assessing the patency of the airway. Patients with signs and symptoms suggestive of significant injuries should have an electrocardiogram, arterial blood gas analysis, complete blood cell count, type and cross-match, coagulation profile, and biochemistry testing, including electrolytes, glucose, and liver and renal function testing. Radiologic studies should include a chest radiograph and an upright abdominal film. Upper gastrointestinal endoscopy should be performed in symptomatic patients or those with visible burns in the mouth or throat. Although the absence of symptoms or signs does not preclude the presence of gastrointestinal burns, in patients with accidental ingestions, such injuries are always of a minor nature and endoscopy is not necessary [17]. Minor symptoms or grade I visible burns following the accidental ingestion of substances shown to have low
toxicity, such as sodium hypochlorite household bleach (less than 10% solution) and hair relaxer gel, do not necessarily require endoscopy, as significant injuries are rare in this setting [36]. However, endoscopy is still recommended if excessive drooling or dysphagia or significant mucosal burns occur after ingestion of these products or if there is doubt about the exact composition of the ingested substance [36]. In contrast, in those with ingestions of strong acids or bases, significant injuries may be present in the absence of clinical findings, and endoscopy is indicated. The optimal timing of endoscopy appears to be 6 to 24 hours after exposure. Because injuries may progress over several hours, endoscopy performed earlier may not detect the full extent of injury and therefore may need to be repeated. If performed later, the risk of perforation is increased.

In the past, it was recommended that the endoscope not be passed beyond the first circumferential or full-thickness lesion because of the risk of iatrogenic perforation. This complication was a significant problem in the days when rigid endoscopes were used. It is extremely rare with flexible endoscopy. Not examining beyond the first significant lesion results in failure to detect more distal lesions of the stomach or duodenum [37]. Flexible endoscopy, preferably using a small-diameter (e.g., pediatric) endoscope, of the entire upper gastrointestinal tract is safe and usually well tolerated [18]. The endoscope should be advanced across the cricopharynx under direct vision to assess for the presence of laryngeal burns [18]. If laryngeal edema or ulceration is noted, the airway should be intubated before endoscopy is continued. Examination should be done gently with minimal air insufflation, avoiding retroversion or retroflexion, and the procedure terminated if the endoscope cannot be easily passed through a narrowed area. Therapeutic dilation of the esophagus on initial endoscopy carries a high risk of perforation and should be avoided [17]. It should also be avoided during the subacute phase (5 to 15 days after ingestion), when the tensile strength of tissues is lowest [18].

A variety of systems for grading gastrointestinal burns have been proposed [17,18]. Some parallel grading systems used for thermal skin burns; others differentiate several levels of ulceration and necrosis (Table 111.3). The important findings are depth of ulceration and presence of necrosis. Injuries that consist only of mucosal inflammation or superficial ulceration and do not involve the muscularis are not at risk for stricture formation [18]. Patients with full-thickness circumferential burns and extensive necrosis are at high risk for perforation and stricture formation. Deep ulceration, whether transmural or not, and discrete areas of necrosis can sometimes lead to stricture formation.

Contrast esophagography is less sensitive than endoscopy in visualizing ulceration but it has a role in the detection of suspected perforation [38]. A water-soluble contrast agent should be used. Cineesophagography can detect esophageal motility disorders, the pattern of which may predict the likelihood of stricture formation. Strictures can be expected to develop in all patients with an atonic dilated or rigid esophagus and in some individuals with abnormal, uncoordinated contractions [39]. Endoscopic ultrasonography can accurately grade corrosive injuries and predict complications [40]. Computed tomography may have a role in the evaluation of caustic injury, but current evidence suggests endoscopy is preferred [41]. Esophageal motility studies may predict the risk of stricture formation in those patients with no peristaltic response; these
motility abnormalities persist for at least 3 months [42].

Evaluation of patients with symptoms and signs of systemic toxicity should include routine monitoring and ancillary testing. The extent and type of testing depend on the nature and severity of clinical abnormalities and the chemical involved. Patients with significant exposure to some phenols (e.g., nitrophenol and pentachlorophenol) and to hydrazine should have methemoglobin level determination.
MANAGEMENT

Advanced life support measures should be instituted as appropriate. Decontamination is the next priority; procedures are specific to the route of exposure. Treatment of systemic poisoning is primarily supportive; in some cases, antidotal therapy may also be necessary.

Irrigation should be performed immediately for eye exposures. The persistence of eye pain despite irrigation for at least 15 minutes indicates significant injury or incomplete decontamination. Failure to irrigate the eye adequately or remove particles after chemical exposure is associated with chronic complications [43]. Up to one-third of patients with lime burns still have particles present in the eye on presentation [43]. All cases in which injury is detected or symptoms persist require ophthalmologic evaluation. Management may consist of topical antibiotics, mydriatics, steroids, and eye patching. The role of neutralization of chemical burns is currently under investigation. Ascorbic acid had been used to treat alkali burns, but its effectiveness has not been well studied, and it cannot be recommended [12].

The initial treatment of dermal exposure is prompt irrigation with copious amounts of water for at least 15 minutes for acid exposures and 30 minutes for alkali. Longer irrigation is recommended for alkalis because they have detergent properties [13]. Although tissue neutralization occurs within 10 minutes with acids and within 1 hour with alkalis in experimental studies, delayed irrigation may be beneficial [44]. Clothes act as a reservoir, and failure to remove them may result in full-thickness burns developing from even mildly corrosive chemicals. Neutralization has been associated with good outcomes [45], but because systematic data on its efficacy are lacking, such therapy cannot be recommended.

In rare cases, water irrigation may be dangerous or ineffective. Metallic lithium, sodium, potassium and cesium, titanium tetrachloride, and organic salts of lithium and aluminum react violently with water; burns caused by these agents should be inspected closely and any particles removed and placed in an anhydrous solution (oil) before the area is irrigated. Alternatively, the area can be wiped with a dry cloth to remove particles and the skin then deluged with water to dissipate any heat. Phenol is not water soluble, and dilution with water may aid its penetration into tissues, increasing systemic absorption [22]. Soaking experimental phenol burns with isopropyl alcohol or polyethylene glycol in mineral oil is superior to rinsing with water [46]. Isopropyl alcohol and polyethylene glycol may be absorbed by burns, and their use should be followed by liberal washing with water. A report describes removing
ready-mixed concrete from skin by soaking or irrigating with 50% dextrose in water [47].

Application of a copper sulfate solution has been suggested to assist in identification and neutralization of white phosphorus particles on the skin, but systemic absorption of copper sulfate can result in massive hemolysis with acute renal failure and death [48]. The use of a Wood’s lamp to detect fluorescent phosphorus particles is safer. White phosphorous burns should be kept wet because phosphorus ignites in dry air. Because sulfur mustard is poorly water soluble, a mild detergent should be used for its removal. Military decontamination kits contain chloramine wipes, which inactivate sulfur mustard [49]. British antilewisite, or dimercaprol, is an effective chelator of lewisite and can be applied topically to the skin or eye [16].

Patients with second- or third-degree skin burns should be referred to a surgeon. Definitive management is the same as for thermal burns, although more aggressive use of early débridement and grafting has been suggested [15].

Despite the rapidity of tissue injury following ingestion, decontamination should be considered. Rinsing with water or saline is recommended for mouth exposures. Dilution by drinking up to 250 mL (120 mL for a child) water or milk is recommended for particulate ingestion, because the corrosive may adhere to the esophageal wall. Although this procedure exposes the stomach to the corrosive agent, it further dilutes the substance. Because the efficacy of dilution is greatest if performed within 5 minutes of exposure and declines rapidly thereafter, it is reasonable to use any drinkable beverage, except carbonated ones, if water or milk is not immediately available. The role of dilution for liquid ingestion is less clear, but it is usually recommended. It may, however, promote emesis and may not be effective in limiting tissue damage unless undertaken within minutes of injury. Emesis is contraindicated because of the risk of aspiration and its association with an increased severity of esophageal and laryngeal burns [19].

The administration of weak acids or bases can neutralize, as well as dilute, ingested corrosives [37]. Although weak acids are more effective than milk or water in neutralizing the pH, neutralization, which is accompanied by the production of heat, could lead to thermal injury in addition to corrosive effects. The heat generated by in vitro neutralization is small (less than 3°C) for liquid alkali but may be greater for solid forms [37]. The benefit of such therapy is unknown and not recommended.

Using a nasogastric tube for gastric aspiration, dilution, or lavage is another subject of debate [6]. Esophageal perforation is a potential complication, but no cases of nasogastric tube perforation have been reported. Placement of a gastric tube with fluoroscopic or endoscopic guidance has been suggested, but the blind, gentle introduction of a
small-bore tube in a cooperative patient, particularly for a large acid ingestion, also appears to be safe [17]. If inserted, the tube should be firmly taped in place to avoid motion. Gastric contents should be aspirated. Dilution or lavage with small aliquots (120 to 250 mL) of water can then be performed.

Activated charcoal does not adsorb inorganic acids or alkali. In addition, because it interferes with endoscopic evaluation, unless a corrosive has a significant systemic toxicity and is known to be bound by activated charcoal, this agent should be avoided. Symptomatic patients should otherwise be given nothing by mouth before endoscopy.

Corticosteroids have been used to reduce the incidence and severity of esophageal strictures after alkali burns. Such therapy is based on studies showing a decrease in stricture formation in animals pretreated with steroids [50]. Because strictures do not develop in patients with first-degree esophageal burns, steroids are not indicated in those with such findings [51]. Similarly, steroids do not appear to influence the development of esophageal strictures after extensive deep ulceration or necrosis [51], and hence they are not recommended in patients with these injuries. Studies on the efficacy of steroids in patients with injuries of moderate severity have yielded conflicting results. Most have been retrospective and poorly controlled. There have been four prospective controlled studies comparing steroids to placebo for prevention of strictures. Two studies suggest no effect of steroids [52,53]. An older small study suggested a small decrease in the percentage of patients who will develop esophageal strictures [54]. A recent well-designed study found a 20% decrease in strictures and a decrease in the need for parenteral nutrition with high-dose methylprednisilone (1 g/1.73 m² IV per day for 3 days) in addition to ranitidine, ceftriaxone, and total parenteral nutrition [54]. One comparative study suggested a 30% absolute risk reduction in risk of stricture with dexamethasone (1 mg per kg per day) compared with prednisolone (2 mg per kg per day) [55]. A survey of emergency surgeons found that approximately half use steroids [56]. Overall, the data are inconclusive, and no definitive recommendations on the effectiveness of steroids can be provided.

If steroids are to be administered, it appears that patients with grade 2b esophageal injury (submucosal burns, ulcerations, and exudates that are circumferential) are the most likely to benefit [54]. Although prior recommendations suggested that therapy should be continued for at least 10 days [51], the most recent study suggests that 3 days of high-dose methylprednisilone is effective.
The decision to administer steroids should be based on endoscopic evaluation. Patients with no injury or mucosal inflammation or small areas of superficial ulceration are not at risk for strictures or perforation and require supportive therapy only. Symptomatic relief can be provided with antacids, sucralfate, histamine-2–blockers (H₂-blockers), or analgesics. Patients with persistent symptoms or inconclusive findings on endoscopy should be admitted for observation. If symptoms persist, endoscopy should be repeated. Patients can commence oral fluids when they are able to swallow their own secretions. They can be discharged when tolerating oral fluids.

Prophylactic antibiotics have also been advocated for patients with significant gastrointestinal injuries. Their benefits have not been studied in humans, and opinions differ as to their value. Controlled animal experiments have shown a combination of steroids and antibiotics to give the best outcome with respect to stricture formation and mortality [57] and suggest that a broad-spectrum antibiotic (e.g., a second-generation cephalosporin) should be administered, particularly in those treated with steroids.

Patients with deep discrete ulcerations, circumferential or extensive superficial ulcerations, or small isolated areas of necrosis who are at risk for stricture formation should be given nothing by mouth. Fluids, analgesics, and H₂-blockers should be administered parenterally. Intravenous steroids and antibiotics should also be considered for those with alkali burns. Patients with deep transmural ulceration or necrosis are at risk for perforation as well as stricture formation. Although the use of steroids for this group is potentially hazardous and not recommended, antibiotics should be given along with other supportive measures. Nutritional support, either parenteral or by jejunostomy feeding tube, may be required.

Surgical exploration is indicated if perforation or penetration into surrounding tissues is suspected by findings such as fever, progressive abdominal or chest pain, hypotension, or signs of peritonitis or proved by endoscopic or radiographic findings. Tracheoesophageal fistulas are usually fatal unless recognized early and repaired, although one case reported successful conservative treatment [35]. Laparotomy and early excision have been suggested for patients with extensive full-thickness necrosis, but an advantage of this approach over more conservative treatment is not clear [58]. The mortality for patients who have major emergency surgery is 9% to 66% [58,59].

Stricture formation is usually treated with endoscopic dilatation beginning 3 to 4 weeks after ingestion. An average of eight sessions is required, and recurrence is common in the first 12 months [60]. In a group of 195 patients with corrosive-induced esophageal strictures, the risk of perforation for each dilatation session was 1.3%, but, because of
the requirement for multiple dilations, the risk per patient was 17% [60]. Perforations were most likely to occur during the first three dilations. Features of perforation include dyspnea, malaise, tachycardia, fever, and subcutaneous crepitations. The majority are detected during the procedure or by the presence of pneumomediastinum, or pneumothorax or hydrothorax on chest radiograph, but occasionally contrast esophagography or esophagoscopy is required for confirmation. The death rate from perforation is 16% to 23% [60]. Early or prophylactic bougienage is of unclear benefit and has been associated with an increased risk of perforation. One study has shown a decrease in the number of dilatations required following interlesional steroid injection [61].

Placement of specialized nasogastric tubes or stents has lowered the rate of stricture formation in uncontrolled clinical trials and is superior to steroids in animal experiments [62]. An additional benefit of combining the use of a stent with systemic steroids has been suggested [62]. Sucrafate, H₂ histamine antagonists, and proton pump inhibitors are of unproven value.

If the patient has severe injury or perforation, surgical management may be required. Occasionally, resection and end-to-end anastomosis are possible, but usually extensive reconstruction, with colonic interposition, is necessary. The overall mortality from colonic replacement surgery is approximately 3% and commonly results from sepsis secondary to anastomosis leakage or colonic graft necrosis [63]. Gastrectomy or gastrojejunostomy may also be required if gastric outlet obstruction develops [64]. Early definitive surgery for gastric outlet obstruction appears to be more advantageous than staged surgery [65]. Endoscopic balloon dilation may be an acceptable alternative procedure [66]. Diode laser-assisted radiolysis using a rigid endoscope has also been used to treat strictures successfully [67].

Supportive management is the mainstay of treatment for systemic toxicity. Heavy metal, cyanide, and hydrogen sulfide poisoning may require antidotal therapy (see Chapter 125). Neurologic toxicity due to hydrazine may respond to intravenous pyridoxine, administered at an initial dose of 25 mg per kg repeated in several hours, if necessary [54] (see Chapter 125). Methemoglobinemia may require treatment with methylene blue (see Chapter 125).

15. Sawhney CP, Kaushish R: Acid and alkali burns: considerations in

This chapter focuses on the aspects of acute poisoning by arsenic, lead, and mercury that are potentially life threatening or may lead to permanent organ damage and hence require immediate, usually intensive, medical care. Reviews of the evaluation and management of asymptomatic exposures and nonacute poisoning can be found elsewhere.

ARSENIC

Exposure to arsenic may come from natural sources, industrial processes, commercial products, food, or intentionally administered sources either with a benevolent (acute promyelocytic leukemia [APL] treatment, folk, or naturopathic remedies) or malevolent intent. Today, acute arsenic poisoning is most commonly the result of an accidental ingestion or the result of suicidal or homicidal intent.

Pharmacology

Arsenic compounds can be classified into three major groups: inorganic, organic, and arsine gas ($\text{AsH}_3$). The latter is discussed separately. Arsenic compounds can also be classified by their valence state. The three most common valence states are the metalloid (elemental [0] oxidation state), arsenite (trivalent [+3] state), and arsenate (pentavalent [+5] state). In general, the arsenic compounds can be arranged in order of decreasing toxicity: inorganic trivalent compounds, organic trivalent compounds, inorganic pentavalent compounds, organic pentavalent compounds, and elemental arsenic. Trivalent arsenic is generally two- to tenfold more toxic than pentavalent arsenic. The minimum oral lethal human dose of arsenic trioxide (trivalent) is probably between 10 and 300 mg. Some marine organisms and algae contain large amounts of organic arsenic in
the form of arsenobetaine, a trimethylated arsenic compound, and arsenocholine. Arsenobetaine and arsenocholine are excreted unchanged in the urine, with total clearance in about 2 days, and exert no known toxic effects in humans.

The major routes of entry into the human body are ingestion and inhalation. Soluble forms of ingested arsenic are 60% to 90% absorbed from the gastrointestinal (GI) tract. The amount of arsenic absorbed by inhalation is also thought to be in this range. Toxic systemic effects have been reported from rare occupational accidents in which arsenic trichloride or arsenic acid was splashed on worker’s skin.

After absorption, arsenic is bound to proteins in the blood and redistributed to the liver, spleen, kidneys, lungs, and GI tract within 24 hours. Clearance from these tissues is dose dependent. Two to 4 weeks after exposure ceases, most of the arsenic remaining in the body is found in keratin-rich tissues (e.g., skin, hair, nails).

Both forms of arsenic, arsenite and arsenate, undergo biomethylation in the liver to monomethylarsonic acid (MMA) and dimethylarsinic acid (DMA). The methylation process may represent detoxification because the metabolites exert less acute toxicity in experimental lethality studies. The liver’s efficiency for methylation decreases with increasing arsenic dose. When the methylating capacity of the liver is exceeded, exposure to excess concentrations of inorganic arsenic results in increased retention of arsenic in soft tissues.

Arsenic is eliminated from the body primarily by renal excretion. Urinary arsenic excretion begins promptly after absorption, and depending on the amount of arsenic ingested, urinary arsenic excretion may remain elevated for 1 to 2 months. After acute intoxication by inorganic arsenic, arsenic is excreted in the urine as inorganic arsenic, MMA and DMA, but their proportion varies with time [1]. During the first 2 to 4 days after the intoxication, arsenic is mainly excreted in the inorganic form. This is followed by a progressive increase of the proportion excreted as MMA and DMA, reaching about 50% of the total arsenic excreted after 4 days and 90% between 6 and 9 days; mainly in the form of DMA. Pentavalent arsenic is cleared more rapidly than trivalent arsenic. Because arsenic is quickly cleared from the blood, blood concentrations may be normal, although urine concentrations remain markedly elevated. Renal dysfunction may be a major impediment to normal elimination of arsenic compounds.

Inorganic arsenic can cross the human placenta. This was evident by the high arsenic concentrations found in a neonate following acute maternal arsenic intoxication.

There are two major mechanisms by which arsenic compounds appear to produce injury involving multiorgan systems. It is believed that arsenic’s overt toxicity is related to its reversible binding with sulfhydryl
enzymes, leading to the inhibition of critical sulfhydryl-containing enzyme systems. Trivalent arsenite is particularly potent in this regard. The pyruvate and succinate oxidation pathways are particularly sensitive to arsenic inhibition. Dihydrolipoate, a sulfhydryl cofactor, appears to be a principal target. Normally, dihydrolipoate is oxidized to lipoate via a converting enzyme, dihydrolipoate dehydrogenase. Arsenic reacts with both dihydrolipoate and dihydrolipoate dehydrogenase, preventing the formation of lipoate. Lipoate is involved in the formation of key intermediates in the Krebs cycle. As a result of lipoate depletion, the Krebs cycle and oxidative phosphorylation are inhibited. Without oxidative phosphorylation, cellular energy stores (adenosine triphosphate [ATP]) are depleted, resulting in metabolic failure and cell death.

The other major mechanism by which arsenic is believed to produce cellular injury is termed *arsenolysis*. Pentavalent arsenate can competitively substitute for phosphate in biochemical reactions. During oxidative phosphorylation, energy is produced and stored in the form of ATP. The stable phosphate ester bond in ATP can be replaced by an arsenate ester bond. However, the high energy stored in the arsenate ester bond is wasted because it is unstable and rapidly hydrolyzed. Cellular respiration is stimulated in a futile attempt to restore this wasted energy. In effect, trivalent arsenic compounds inhibit critical enzymes in the Krebs cycle, leading to inhibition of oxidative phosphorylation, and pentavalent arsenic compounds uncouple oxidative phosphorylation by arsenolysis. This results in the disruption of cellular oxidative processes, leading to endothelial cellular damage. The fundamental lesion seen clinically is loss of capillary integrity, resulting in increased permeability of blood vessels and tissue hypoxia, leading to generalized vasodilation, transudation of plasma, hypovolemia, and shock.

In vitro, the effects of arsenic trioxide on repolarizing cardiac ion currents appear to be one of antagonism on both $I_{Kr}$ and $I_{Ks}$ as well as activation of $I_{K-ATP}$, which maintains normal repolarization [2]. In addition, arsenic trioxide increases cardiac calcium currents and reduces surface expression of the cardiac potassium channel human ether-a-go-go-related gene. The variability in QTc interval prolongation and the onset of ventricular dysrhythmias during arsenic therapy may represent these competing effects.

Clinical Toxicity
The most prominent clinical findings associated with acute arsenic poisoning are related to the gastrointestinal (GI) tract. Some arsenicals
are corrosive. Acute ingestion may lead to oral irritation and a burning sensation in the mouth and throat. A metallic taste and/or a garlicky odor to the breath have been described, but often are not present. Nausea, vomiting, and abdominal pain are common. The toxic effects of arsenic on the GI tract are manifested as increased peristalsis and profuse watery stools and bleeding. In serious cases, hemorrhagic gastroenteritis may ensue within minutes to hours after acute ingestion. Nausea, vomiting, and severe hemorrhagic gastroenteritis can all lead to profound intravascular volume loss, resulting in hypovolemia shock, which is the major cause of mortality and morbidity.

Noncardiogenic pulmonary edema may occur from increased capillary permeability, and cardiogenic pulmonary edema may occur from myocardial depression. Electrocardiogram (ECG) changes associated with arsenic poisoning consist of nonspecific ST- and T-wave changes, sometimes mimicking ischemia or hyperkalemia and QTc prolongation [3]. These ECG abnormalities are reported to occur in half the patients with arsenic poisoning, and these ECG changes may be evident from 4 to 30 hours postingestion, persisting for up to 8 weeks.

At least six cases of arsenic-induced polymorphic ventricular tachycardias consistent with torsades de pointes have been reported. In all these cases, QTc prolongation was evident on the admission ECG. Except in the case of the patient who presented with cyanosis and cardiorespiratory arrest, peripheral neuropathy was a prominent finding on physical examination at the time of hospital admission and the polymorphic ventricular tachydysrhythmias were ultimately self-limited. Although these cases were able to document as to when during the hospital course torsades de pointes were observed, the time between arsenic exposure and the onset of cardiac dysrhythmias can only be speculated.

Arsenicals have been used as part of traditional Chinese medicine for 2,400 years. They became a therapeutic mainstay for a variety of infectious and malignant diseases during the 18th, 19th, and early 20th centuries (e.g., Fowler’s solution [potassium bicarbonate-based solution of arsenic trioxide] as treatment for chronic myeloid leukemia). Arsenic compounds fell into disuse in the 1930s with the advent of radiotherapy and cytotoxic chemotherapeutic agents and concerns about arsenic’s toxicity and carcinogenicity. However, arsenic trioxide has attracted renewed attention as a treatment for APL on the basis of impressive results from clinical studies in China and the United States [2]. Arsenic trioxide is licensed for use in patients with relapsed or refractory APL. Arsenic trioxide is administered as an infusion 0.15 mg per kg until bone marrow remission or a cumulative maximum of 60 days or associated with adverse drug events (Table 112.1) [2]. Prolongation of the QTc was observed between 1 and 5 weeks after arsenic trioxide infusion, and then
returned towards baseline by the end of 8 weeks.

| TABLE 112.1 Adverse Drug Events Associated with Arsenic Trioxide Induction Therapy |
|---------------------------------|---------------------------------|
| Cardiovascular                  | QTc prolongation (≥500 ms), torsades de pointes, sudden death, tachycardia |
| Hematologic                     | Hyperleukocytosis (10,000–170,000 cells/μL) |
| Nervous system                  | Peripheral neuropathy, headache |
| Metabolic                       | Hypokalemia, hypomagnesemia, hyperglycemia |
| APLDS                           | Fever, pleural or pericardial effusion, pleural infiltrates, respiratory distress, weight gain, musculoskeletal pain |
| GI                              | Nausea, vomiting, diarrhea |
| Dermatologic                    | Skin rash |

APLDS, acute promyelocytic leukemia differentiation syndrome; GI, gastrointestinal.

Both acute and chronic arsenic poisoning may affect the hematopoietic system. A reversible bone marrow depression with pancytopenia, particularly leukopenia, may occur. However, it is the chronic form that is usually associated with severe hematopoietic derangements. A wide variety of hematologic abnormalities have been described with arsenic poisoning, including anemia, absolute neutropenia, thrombocytopenia, eosinophilia, and basophilic stippling [4]. Anemia is, in part, due to an increase in hemolysis and disturbed erythropoiesis/myelopoiesis with reticulocytosis and predominant normoblastic erythropoiesis. Accelerated pyknosis of the normoblast nucleus, karyorrhexis, is characteristic of arsenic poisoning, and the typical “cloverleaf” nuclei may be evident. Hematologic findings may appear within 4 days after acute arsenic ingestion, and in the absence of any specific therapy, erythrocytes, leukocytes, and thrombocytes were reported to return to normal values within 2 to 3 weeks after discontinuing arsenic exposure.
Neurologic manifestations of arsenic poisoning have included confusion, delirium, convulsions, encephalopathy, and coma [5]. Neuropathy is usually not the initial complaint associated with acute arsenic poisoning. Arsenic-induced polyneuropathy has traditionally been described as an axonal-loss sensorimotor polyneuropathy (low-amplitude/unelicitable sensory and motor conduction responses, often with preserved motor conduction velocities). The first symptoms of neuropathy have been reported to appear 1 to 3 weeks after the presumptive arsenic exposure [5]. Clinical manifestations span the spectrum from mild paresthesia with preserved ambulation to distal weakness, quadriplegia, and respiratory muscle insufficiency. Arsenic neuropathy is a symmetrical sensorimotor neuropathy, with the sensory component being more prominent in a “stocking-and-glove” distribution [6]. This polyneuropathy may progress in an ascending fashion to involve proximal arms and legs. Dysesthesias begin in the lower extremities, with severe painful burning sensation occurring in the soles of the feet. There is loss of vibration and positional sense, followed by the loss of pinprick, light touch, and temperature sensation. Motor dysfunction is characterized by the loss of deep tendon reflexes and muscle weakness. In severe poisoning, ascending weakness and paralysis may occur and involve the respiratory muscles, resulting in neuromuscular respiratory failure [7]. It has been reported that many of the patients with arsenic neuropathy were initially thought to have Guillain–Barré disease [5,7].

Because the fundamental lesion in arsenic toxicity is the loss of capillary integrity, increased glomerular capillary permeability may result in proteinuria. However, the kidneys are relatively spared from the direct toxic effects of arsenic. Hypovolemic shock associated with the prominent GI symptoms may lead to hypoperfusion of the kidneys, resulting in oliguria, acute tubular necrosis, and renal insufficiency or failure. The kidneys are the main route of excretion for arsenic compounds. Normal-functioning kidneys can excrete more than 75 mg of arsenic in the first 24 hours [8]. Because of shock and decreased glomerular filtration rate and depending on the dose of arsenic ingested, peak urinary arsenic excretion may often be delayed by 2 to 3 days. Hemodialysis contributes minimally to arsenic clearance compared with the normal-functioning kidneys. Accordingly, arsenic removal by hemodialysis has been reported to exceed its daily urinary excretion in patients with acute renal failure.

Dermal changes occurring most frequently in arsenic-exposed humans are hyperpigmentation, hyperkeratosis, and skin cancer [9]. The lesions usually appear 1 to 6 weeks after the onset of the illness. In most cases, a
diffuse, branny desquamation develops over the trunk and extremities; it is dry, scaling, and nonpruritic. Patchy hyperpigmentation—dark-brown patches with scattered pale spots, sometimes described as “raindrops on a dusty road”—occurs particularly on the eyelids, temples, axillae, neck, nipples, and groin. Arsenic hyperkeratosis usually appears as cornlike elevations, less than 1 cm in diameter, occurring most frequently on the palms of the hands and on the soles of the feet. Most cases of arsenic keratoses remain morphologically benign for decades, and in other cases, marked atypia (precancerous) develops and appears indistinguishable from Bowen’s disease—an in situ squamous cell carcinoma. Skin lesions take several years to manifest the characteristic pigmented changes and hyperkeratoses, whereas it may take up to 40 years before skin cancer becomes evident. Brittle nails with transverse white bands (leukonychia striata arsenicalis transversus), Reynolds–Aldrich–Mees lines, appearing on the nails have been associated with arsenic poisoning. It reflects transient disruption of nail plate growth during acute poisoning. Leukonychia striata arsenicalis transversus takes about 5 to 6 weeks to appear over the lunulae after an acute poisoning. Thinning of the hair and patchy or diffuse alopecia are also associated with arsenic poisoning.

Diagnostic Evaluation

The temporal sequence of organ system injury may suggest acute arsenic intoxication. After a delay of minutes to hours, severe hemorrhagic gastroenteritis becomes evident, which may be accompanied by cardiovascular collapse or death. Bone marrow depression with leukopenia may appear within 4 days of arsenic ingestion and usually reaches a nadir at 1 to 2 weeks. Encephalopathy, congestive cardiomyopathy, noncardiogenic pulmonary edema, and cardiac conduction abnormalities may occur several days after improvement from the initial GI manifestations. Sensorimotor peripheral neuropathy may become apparent several weeks after resolution of the initial signs (gastroenteritis or shock) of intoxication resulting from ingestion.

The differentiation between arsenic neuropathy and Landry–Guillain–Barré disease is based on clinical and laboratory findings in that arsenic neuropathy rarely involves the cranial nerves, sensory manifestations are more prominent, weakness in the distal portions of the extremities is more severe, and the cerebrospinal fluid protein concentrations are usually less than 100 mg per dL [5,6].

Laboratory investigation should include complete blood count with peripheral smear, electrolytes, liver enzymes, creatine phosphokinase, arterial blood gas, renal profile with urine analysis, electrocardiogram (ECG), chest radiograph, and blood and urine arsenic concentrations. Nerve conduction velocity studies may be indicated if peripheral
neurologic symptoms are present. Some arsenic compounds, particularly those of low solubility, are radiopaque, and if ingested they may be visible on an abdominal radiograph.

The most important diagnostic test is urinary arsenic measurement. Urine arsenic concentrations may be measured as “spot,” that is, the concentration in a single-voided urine specimen, reported in micrograms per liter. Urine arsenic concentrations may also be measured as a timed urine collection, or the concentration in urine collected during a 12- to 24-hour period, reported in micrograms per 12 or 24 hours. The quantitative 24-hour urine collection is considered the most reliable. In an emergency situation, the spot urine sample may be of value. Normal total urinary arsenic values are $<50 \mu g$ per L or $<25 \mu g$ per 24 hours. In the first 2 to 3 days following acute symptomatic intoxications, total 24-hour urinary arsenic excretion is typically in excess of several thousand micrograms, with spot urine concentration $>1,000 \text{ mg per L}$, and depending on the severity, it may not return to background for weeks. Recent ingestion of seafood may markedly elevate urinary arsenic values for the next 2 days. Therefore, it is important to take a careful dietary history of the past 48 hours when only total urinary arsenic is measured. Speciation of the urinary arsenic can be performed in some laboratories. Otherwise, the urinary arsenic test should be repeated in 2 to 3 days. Whole blood arsenic, normally $<1 \mu g$ per dL, may be elevated early on in acute intoxication. However, blood concentrations decline rapidly to normal values despite elevated urinary arsenic excretion and continuing symptoms. Elevated arsenic content in hair and nail segments, normally $<1 \text{ part per million}$, may persist for months after urinary arsenic values have returned to background. However, caution should be exercised when interpreting the arsenic content obtained from hair and nails because the arsenic content of these specimens may be increased by external exposure.

**Management**

The management of acute arsenic poisoning relies on supportive care and chelation therapy. Treatment begins with eliminating further exposure to the toxin and providing basic and advanced life support. Anyone with arsenic intoxication necessitating hospitalization should initially be admitted to an intensive care unit (ICU).

Gastric lavage should be performed following an acute ingestion and should be considered if the ingestion has been within the past 24 hours because some arsenic compounds of low solubility may be retained in the stomach for a prolonged period. Frequently, seriously poisoned patients will have already vomited, evacuating some of their stomach contents. Activated charcoal and cathartics may be used, but their efficacy is
unclear. When there is evidence of a heavy metal burden on an abdominal radiograph, whole-bowel irrigation (WBI) with a polyethylene glycol electrolyte solution may rapidly help clear the GI tract of the metallic load. However, the absence of radiopacities on the abdominal radiograph is nondiagnostic, and WBI should still be considered when there is a definite history that a poorly soluble arsenic compound has been ingested.

Intravascular volume depletion may require aggressive replacement with crystalloids, colloids, and blood products. Vasopressors are recommended for refractory hypotension. Invasive monitoring of the patient’s hemodynamic status may be necessary.

For acute arsenic poisoning, extended cardiac monitoring for ventricular dysrhythmias is indicated for all patients who have prolonged QTc on their ECG. Electrolyte abnormalities—in particular, hypokalemia and hypomagnesemia—should be aggressively corrected, and concomitant QTc interval-prolonging drugs should be avoided. Serum potassium concentrations should be maintained at >4.0 mmol per L and serum magnesium concentrations at >0.74 mmol per L (1.8 mg per dL). There are no good data to indicate that suppression of ventricular dysrhythmias decreases mortality rates. If dysrhythmias occur, they should be treated according to current advanced cardiac life support guidelines. Type IA antidysrhythmic cardiac medications should be avoided because these drugs may themselves cause further QTc prolongation and worsen the polymorphic ventricular tachycardia. Lidocaine, magnesium, and isoproterenol have been used with limited success in the management of arsenic-induced torsades de pointes. A transvenous pacemaker for overdrive pacing may be necessary. Noncardiogenic and cardiogenic pulmonary edema should be managed according to current guidelines. In patients receiving arsenic trioxide induction therapy who develop prolonged QTc of more than 500 ms on ECG, the risk/benefits of continuing therapy should be considered.

Hematologic effects of arsenic poisoning should be managed symptomatically with blood component therapy and antibiotics as necessary for severe anemia, bleeding, or infections.

Patients with arsenic polyneuropathy should receive analgesics for pain and physical therapy for rehabilitation. Patients with polyneuropathy associated with severe arsenic poisoning should be observed closely for respiratory dysfunction. Neuromuscular respiratory failure may be delayed 1 to 2 months after the initial presentation. In cases in which there is progressive sensorimotor dysfunction, particularly ascending
weakness, respiratory muscle function should be monitored carefully. When there is evidence of impending neuromuscular respiratory failure (e.g., negative inspiratory force <25 cm H₂O or vital capacity <20 mL per kg), aggressive supportive measures should be initiated in a timely fashion.

Patients with renal failure may benefit from hemodialysis. However, hemodialysis has limited use when normal renal function is present. Hemodialysis (initiated 24 to 96 hours post-ingestion) has been reported to remove about 4 mg of arsenic during a 4-hour period in patients with established renal failure. It should not be surprising that only small amounts of arsenic are removed by dialysis as minimal amounts of arsenic are left in the central compartment once tissue distribution and equilibration is complete.

The principle behind chelation therapy is to increase excretion of the metal and decrease the target organ’s metal burden. A chelator is an organic compound that has a selective affinity for heavy metals. It competes with tissues and other compounds containing thiol groups for metal ions, removes metal ions that previously have been bound, and binds with the metal ion to form a stable complex (chelate), rendering the metal less reactive and less toxic. The metal–chelator complex is water soluble and can be excreted in the urine, bile, or both, and to some extent it can be removed by hemodialysis.

Dimercaprol (2,3-dimercapto-1-propanol [British anti-Lewisite, BAL]) is the traditional chelating agent that has been used clinically in arsenic poisoning. In humans and animal models, the antidotal efficacy of BAL has been shown to be most effective when it was promptly administered (i.e., minutes to hours) after acute arsenic exposure [10]. In cases of suspected acute symptomatic intoxication, treatment should not be delayed while waiting for specific laboratory confirmation. BAL is administered parenterally as a deep intramuscular (IM) injection. The initial dose is 3 to 5 mg per kg every 4 hours, gradually tapering to every 12 hours during the next several days. As the patient improves, this may be switched to 2,3-dimercaptosuccinic acid (DMSA; succimer) (see “Lead” section). In the United States, DMSA is available only in an oral formulation. This precludes its use in acute severe arsenic intoxication when shock, vomiting, gastroenteritis, and splanchnic edema limit GI absorption. For patients with stable GI and cardiovascular status, a dose regimen of 10 mg per kg every 8 hours for 5 days, reduced to every 12 hours for another 2 weeks, may be employed. D-Penicillamine has also been reported to be successful adjunct treatment in cases of acute pediatric arsenic toxicity [11]. Oral D-penicillamine, 25 mg per kg every 6 hours (maximum of 1 g per day), should be used if BAL or DMSA is unavailable or if the patient is unable to tolerate these medications. Disadvantages in using D-penicillamine include that it is administered
only by the oral route, it is usually not well tolerated, it should be used with caution in patients who are allergic to penicillin, and it entails potential enhanced absorption of arsenic-chelate complex. Adverse drug events associated with long-term D-penicillamine treatment include fever, pruritus, leukopenia, thrombocytopenia, eosinophilia, and renal toxicity. A complete blood count and renal function tests should be monitored weekly during D-penicillamine therapy.

BAL and its metal chelate dissociate in an acid medium, and maintenance of an alkaline urine may protect the kidneys during chelation therapy. BAL should be administered with caution in patients with glucose-6-phosphate dehydrogenase deficiency because it may cause hemolysis. The adverse drug events of BAL appear to be dose dependent, with an incidence of >50% at a dose of 5 mg per kg [12]. The reported adverse drug events include pain at the injection site; systolic and diastolic hypertension with tachycardia; nausea; vomiting; headache; burning or constricting sensation in the mouth, throat, and eyes; lacrimation; salivation; rhinorrhea; muscle aches; tingling of the extremities; pain in the teeth; sense of constriction in the chest; abdominal pain; sterile or pyogenic abscesses at the site of injection; and a feeling of anxiety or unrest. In addition to these adverse drug events, a febrile reaction may occur in children. These signs and symptoms are most severe within 30 minutes after administration of BAL and usually dissipate within 1 to 1.5 hours. The adverse drug events may be lessened by the use of epinephrine or by pretreatment with antihistamine or ephedrine [12].

The therapeutic end points of chelation are poorly defined. Usually 24-hour urinary arsenic excretion is followed before, during, and after chelation with continued chelation therapy until the urinary arsenic excretion is <25 μg per 24 hours. Alternatively, when it can be demonstrated that >90% of the total arsenic excreted in the urine is in the form of MMA and DMA, endogenous biomethylation and detoxification may obviate the need for continued chelation [1]. This is likely to occur during the recovery period when urinary inorganic arsenic concentration has declined to less than 100 μg per 24 hours or total blood arsenic concentration is less than 200 μg per L [1].

Chelation therapy may not reverse neuropathy [5,6]. Early treatment may prevent incipient peripheral neuropathy in some, but not all, patients. However, the value of chelation in the treatment of an established arsenic neuropathy has not been demonstrated. In cases of chronic symptomatic arsenic intoxication with high urinary arsenic excretion, an empiric course of chelation may be warranted.
ARSINE GAS

Arsine (AsH₃) is a colorless, nonirritating, inflammable gas with a garlicky odor. It is considered to be the most toxic of the arsenic compounds. The garlic-like odor is not a reliable indicator of exposure because hazardous effects may occur below the odor threshold. Exposure usually occurs in industrial/occupational settings, such as smelting and refining of metals and ores, galvanizing, soldering, etching, lead plating, metallurgy, burning fossil fuels, and the microelectronic/semiconductor industry. (Computer chips made of gallium arsenide are etched with strong acids.)

Pharmacology

Arsine binds to red blood cells (RBCs), causing a rapid and severe Coombs’ negative hemolytic anemia. The exact mechanism by which arsine is lytic to the RBC has not been definitively elucidated. In vitro and animal studies indicate that hemolysis requires the presence of oxygen, there is a reduction in the RBCs’ glutathione concentration, which is time and concentration dependent on arsine gas exposure, and there is an inverse correlation between the reduced glutathione concentration and the extent of hemolysis. These findings are consistent with a mechanism of oxidative stress-induced damages to the RBCs, resulting in hemolysis.

Toxic concentrations of arsine appear to have deleterious effect on the kidneys. Acute renal failure was often a common cause of death before advent of hemodialysis. Postulated mechanisms of arsine-induced renal failure include direct toxic effects of arsine on renal tubular cell respiration, hypoxia due to the hemolytic anemia, and the massive release of the “arsenic–hemoglobin–haptoglobin complex” precipitating in the tubular lumen, resulting in a toxic effect on the nephron. Depending on the severity, renal failure may be evident by 72 hours from the time of exposure.

Clinical Toxicity

The severity and time to manifestation of arsine poisoning depend on the concentration and duration of the exposure. After an acute massive
exposure, death may occur without the classic signs and symptoms of arsine poisoning. It is believed that after low-concentration exposures, arsine is rapidly and efficiently cleared from plasma into the RBCs. However, high concentrations of arsine may exceed the binding capacity of the erythrocytes, and the gas may directly damage vital organs. In cases in which signs and symptoms of arsine poisoning develop over time, the associated morbidity and mortality is partly related to the consequences of its hematologic and renal effects. In general, after a significant exposure to arsine, there is usually a delay of 2 to 24 hours before symptoms of arsine poisoning become apparent.

Initial complaints include dizziness, malaise, weakness, dyspnea, nausea, vomiting, diarrhea, headache, and abdominal pain. Dark-red discoloration of the urine, hemoglobinuria, and/or hematuria frequently appear 4 to 12 hours after inhalation of arsine. Depending on the severity of the exposure, reddish staining of the conjunctiva and dusky bronze skin may become apparent within 12 to 48 hours [15]. However, the sensitivity of this sign is unclear. The conjunctival and skin discoloration is due to the presence of hemoglobin. This should be distinguished from true jaundice due to the presence of bilirubin. The triad of abdominal pain, hematuria, and bronze-tinted skin is recognized as a characteristic clinical feature of arsine poisoning [13].

In one study, ECG changes associated with arsine poisoning included peaked T waves, particularly in the precordial leads. The most pronounced T-wave changes occurred between the 2nd and the 12th day after exposure. The severity of illness did not correlate with the height of the T wave. There was no delay in atrioventricular or intraventricular conduction times. There was progressive normalization of the T-wave amplitude evident on the weekly follow-up ECG. The exact cause of the ECG change remains speculative.

Management

All patients hospitalized for arsine poisoning should be admitted in the ICU. The management of arsine poisoning should be directed at preventing further exposure to the gas, restoring the intravascular RBC concentration, monitoring the serum potassium, preventing further renal insult, and providing aggressive supportive care. In cases of acute and severe arsine poisoning, exchange transfusion or plasma exchange may be an efficient and effective means of management [13,16,17]. It is important to maintain good urine output (2 to 3 mL/kg/h) at all times. Alkalination of the urine has been recommended to prevent deposition of RBC breakdown products in the kidneys. In situations in which there is evidence of renal insufficiency or failure, both exchange transfusion and hemodialysis may be required. There are practical and theoretic
considerations for using exchange transfusion. It restores the intravascular RBC concentration and removes erythrocyte debris and arsenic–hemoglobin complexes. Hemolysis due to arsine poisoning can be a dynamic process; there is one report of ongoing hemolysis for at least 4 days in patients not selected for exchange transfusion. Theoretic support for the use of exchange transfusion came from animal studies where a large proportion of the fixed arsenic in the blood of animals poisoned with arsine was in a nondialyzable form, and adequate removal of arsine and its associated toxic complexes would be a problem with hemodialysis alone. It has been suggested that with early diagnosis of arsine poisoning and prompt institution of exchange transfusion, the incidence of renal damage and long-term renal insufficiency may be reduced.

The results of using BAL in the treatment of acute arsine poisoning have been disappointing [15,18]. BAL does not appear to afford protection against arsine-induced hemolysis. It remains speculative whether BAL would be of benefit in subacute or chronic arsine poisoning.
LEAD

The use of lead and its environmental contamination has increased dramatically since the beginning of the Industrial Revolution. However, for the past 20 years, environmental and occupational exposure to lead as well as the severity of lead poisoning have decreased because of government regulations and increased public health awareness of the problems associated with lead, especially at low-concentration exposures.

The major environmental sources of lead include vehicle exhaust, paint, food, and water. Combustion of leaded gasoline by motor vehicles produced lead in automobile emissions, which is the main source of airborne lead. Airborne lead can be inhaled directly or deposited in the environment (soil, water, and crops). The content of lead in residential paint was not regulated until 1977. More than half of the older residential and commercial structures built before 1960 have been painted with lead-based paints. With time, flaking, chipping, peeling, and chalking of the paint occurs—a potential source of lead exposure. Industrial use of corrosion-resistant lead paint continues. High-concentration exposure may result from renovation, sandblasting, torching, or demolition of older applications. Food may contain lead that has been deposited in the soil or water. Food may be contaminated with lead when it is harvested, transported, processed, packaged, and prepared. Lead exposure may occur from use of lead-glazed pottery or ceramic ware for cooking and eating as well as from the consumption of food from lead-soldered cans. Water from leaded pipes, soldered plumbing, and water coolers is also a potential source of lead exposure. Some traditional Hispanic, Asian, and Middle Eastern folk medicine has been shown to contain significant amounts of lead. Mexican folk remedies, “azarcon” and “greta,” are prescribed by the local folk healers (curanderos) to treat nonspecific GI symptoms collectively known as “empacho.” Azarcon is a bright-orange powder and greta is a fine yellowish powder. Other names such as alarcon, coral, liga, Maria Luisa, and rueda have been given to these lead-containing folk remedies. In Asian communities, lead-containing folk remedies include bali goli, chuífong tokuwan, ghasard, knadu, pay-loo-ah, and Po Ying Tan. Middle Eastern lead-containing folk medicines include alkohl, cebagin, kohl, saoott, and surma.

The most significant way in which children are exposed to lead is through inhalation and ingestion. Children can ingest chips from lead-painted surfaces, or by mouthing items contaminated with lead from dust, soil, or paint. Some children are given folk remedies containing large quantities of lead. Another potential source of lead exposure in children is the preparation of infant formulas in vessels with lead solder.
Aside from the environmental sources, lead exposure in adults primarily comes from the occupational setting, particularly for electricians; cable splicers; plumbers; lead, copper, zinc, and silver miners; printers; lead smelters and refiners; steel welders and cutters; painters; auto repairers (radiator repair mechanics); sandblasting, demolition, and construction workers; battery manufacturers; solderers; bricklayers; silversmiths; glass manufacturers; and ship builders. One source of lead exposure that is not often considered is retained lead bullets, especially those that are near synovial surfaces.

Hobbies and related activities such as home remodeling, target shooting at indoor firing ranges, stained glass making, glazed pottery making, lead soldering, and making illicitly distilled whiskey (“moonshine”) can potentially subject adults and their families to high concentrations of lead.

Pharmacology

In adults, about 10% of an ingested dose is absorbed, whereas in children, up to 50% may be absorbed. GI absorption may be increased by iron or calcium deficiency and varies directly with the solubility of the lead compound ingested and inversely with particle size. The oral dose associated with the lowest observable effect level in humans is uncertain. Acute human ingestion of 15 g of lead oxide has resulted in fatality.

Inhalation of lead is a significant route of exposure as lead particles (e.g., dust) and fumes can potentially reach the alveoli, where absorption from the lower respiratory tract is nearly complete. Airborne lead particles are usually too large to enter the alveoli of small children. These particles (when inhaled) are returned to the posterior pharynx through ciliary action and swallowed. Dermal absorption of lead is rapid and extensive for alkyl lead compounds, but minimal for inorganic lead.

After absorption, almost all lead in the blood is located within the RBCs [19]. RBC lead has a half-life of 30 to 40 days and is circulated and distributed into soft tissues and bones. The half-life of lead in the soft tissues is about 40 days, whereas the half-life in bones is 20 to 30 years. Hence, blood lead concentration may be declining as the soft tissue and bone burdens are rising. Equilibration between bone and blood lead does occur. The major depot for lead in the body is the skeletal system, which contains more than 90% in adults and more than 70% in children, in terms of the total-body lead burden. The primary sources of lead that cause clinical and subclinical symptoms are the blood and soft tissues. Lead that is deposited and incorporated into the matrix of bone can be
mobilized during pregnancy, lactation, osteoporosis, and prolonged immobilization. In addition, lead that is deposited in bone may have some toxic effects on bone growth and function.

The kidneys filter lead unchanged (with some active tubular transport at high concentrations), and the excretion rate depends on the glomerular filtration rate and renal blood flow. The kidneys account for about 75% of daily lead loss [19]. However, elimination of lead from the body is influenced by the relative concentration of lead in the various body compartments.

Common forms of inorganic lead are generally devoid of significant irritant or corrosive effects. However, alkyl lead compounds may be moderately irritating. The multisystemic toxicity of lead is mediated by at least two primary mechanisms: the inhibition of enzymatic processes, sometimes as a result of sulfhydryl group binding, and interaction with essential cations, in particular calcium, zinc, and ferrous iron. Pathologic alterations in cellular and mitochondrial membranes, neurotransmitter biosynthesis and function, heme biosynthesis, and nucleotide metabolism may also occur.

One of the principal toxic effects of lead is inhibition of enzymes along the heme biosynthesis pathway. Specifically, lead inhibits the enzymes δ-aminolevulinic acid (ALA) dehydrase and ferrochelatase. As a result, δ-ALA cannot be converted to porphobilinogen and iron cannot be incorporated into protoporphyrin IX. This is reflected by a measurable increase in serum ALA and protoporphyrin concentrations. The increase in protoporphyrin forms the basis of the erythrocyte protoporphyrin (EP) test, which has been used to screen for chronic lead exposure. Lead also inhibits the nonenzymatic mobilization of iron stores, which further contributes to the effect of anemia. Impaired heme biosynthesis may have widespread effects because of its impact on the cytochrome systems. In addition, lead appears to shorten erythrocyte survival time by interfering with the sodium–potassium–adenosine triphosphatase pump mechanism and by attaching to RBC membranes, causing increased mechanical fragility and cell lysis. Decreased heme synthesis and increased RBC destruction results in reticulocytosis. Inhibition of pyrimidine-5’-nucleotidase by lead results in accumulation of ribonucleic acid degradation products and aggregation of ribosomes in RBCs, which produce punctate basophilic stippling. However, neither anemia nor basophilic stippling is a sensitive or specific indicator of lead intoxication. Lead-induced anemia results from either a prolonged exposure or a concentrated short-term exposure with a latent period of several weeks.

Lead toxicity produces anatomic lesions in the proximal tubule and loops of Henle, which is characterized by round acidophilic intranuclear inclusion bodies. Most often, lead-induced renal injury is associated with prolonged exposure to large amounts of lead, resulting in progressive
renal insufficiency.

The toxic effects of lead involve both the peripheral nervous system and the central nervous system (CNS). Peripheral nervous system toxicity is known as lead palsy and is due to the degenerative changes in the motoneurons and their axons, with secondary effects involving the myelin sheaths [20]. Lead palsy is usually a pure motor neuropathy and is the result of advanced chronic lead poisoning. Both adults and children can present with CNS dysfunction; however, acute encephalopathy is an unusual feature of adult lead intoxication. Although lead encephalopathy is rare today, it is the most serious consequence of lead poisoning and is probably due to inhibition of the intracellular enzyme systems within the CNS.

Clinical Toxicity

Poisoning is usually the result of continued exposure to small amounts of lead rather than a single acute event. However, acute ingestion can produce lead toxicity. Usually, the clinical presentation of acute lead toxicity appears to be associated with a sharp incremental rise in the concentration of lead in various soft tissues, and this often occurs against the background of chronic lead poisoning.

The multisystemic toxicity of lead presents a spectrum of clinical findings ranging from overt, life-threatening intoxication to subtle, subclinical deficits. Acute ingestion of very large quantities of lead (gram quantities) may cause abdominal pain, toxic hepatitis, and anemia (usually hemolytic).

Subacute or chronic exposure causes nonspecific constitutional symptoms such as fatigue, arthralgias, decreased libido, irritability, impotence, depression, anorexia, malaise, myalgias, weight loss, and insomnia [21]. Gastrointestinal symptoms include nausea, constipation or diarrhea, and intestinal spasm. The intestinal spasm, “lead colic,” can cause severe, excruciating, paroxysmal, abdominal pain. Central nervous system findings range from impaired concentration, visual–motor coordination, and headache, to severe, life-threatening encephalopathy characterized by vomiting, tremors, hyperirritability, ataxia, confusion, delirium, lethargy, obtundation, convulsions, coma, and death. A peripheral motor neuropathy, predominantly affecting the upper extremities, may result in extensor weakness. In rare instances, severe cases may produce frank “wrist drop.” Decreased intelligence, impaired neurobehavioral development, decreased stature or growth, and diminished auditory acuity may occur. Hematologic manifestations include normochromic or microcytic anemia. This may be accompanied by basophilic stippling of the erythrocytes. Nephrotoxic effects include overt reversible acute tubular dysfunction, in particular, Fanconi-like
aminoaciduria in children, and chronic progressive renal interstitial fibrosis following heavy long-term exposure in lead workers. Sometimes hyperuricemia, with or without evidence of gout, may be associated with the renal insufficiency. An association between lead exposure and hypertension may exist in susceptible populations.

Repeated, intentional inhalation of leaded gasoline may result in ataxia, myoclonic jerking, hyperreflexia, delirium, and seizures.

**Diagnostic Evaluation**

Although encephalopathy and abdominal colic following a suspect activity may readily suggest the diagnosis of severe lead intoxication, the nonspecific nature of mild-to-moderate intoxication frequently presents a diagnostic challenge. Exposure is often not suspected, and symptoms are commonly attributed to a “nonspecific viral illness.” Lead intoxication should be considered in patients presenting with multisystem findings including headache, abdominal pain, and anemia, and, less commonly, motor neuropathy, gout, and renal insufficiency. Lead encephalopathy should be considered in any child with delirium or seizures, and milder degrees of intoxication should be considered in children with neurobehavioral deficits or developmental delays. Lead encephalopathy has usually been associated with blood lead concentrations of 100 μg per dL or more [22]. Blood lead concentrations >80 μg per dL are occasionally associated with acute severe illness.

Whole blood lead concentration and EP are the two methods most commonly used in testing for lead intoxication. Whole blood lead concentration is the most useful screening and diagnostic test for acute or recent lead exposure. This test does not measure total-body lead burden, but it does reflect abrupt changes in lead exposure. Elevation in EP (>35 μg per dL) reflects lead-induced inhibition of heme biosynthesis. Because only actively forming erythrocytes are affected, elevations in EP will typically lag behind lead exposure by 2 to 6 weeks. EP value may help distinguish between recent and remote lead exposure. An extremely high whole blood lead concentration in the presence of a normal EP concentration would suggest a recent lead exposure. An elevated EP concentration is not specific for lead exposure and may also occur with iron deficiency. EP is not a sensitive screening tool for low-concentration (<30 μg per dL) lead poisoning. EP and blood lead concentrations should be used as complementary methods of testing for lead intoxication.

Erythrocyte protoporphyrin, free EP, and zinc EP measure the same
basic process and have very similar interpretations, but are not identical. EP is the most precise terminology. Because lead blocks (ferrochelatase) the final step in heme biosynthesis, it was originally thought that “free” EP was formed. However, it was subsequently shown that other porphyrins were measured in minute amounts, and most protoporphyrin had nonenzymatically bound zinc and was therefore not “free.”

Relationships between blood lead concentrations and clinical findings have generally been based on subacute and chronic exposure and not on transiently high values that may result immediately following exposure before tissue equilibration (Table 112.2). Interindividual variability in response is extensive.

Measurement of urinary lead excretion is not very useful in the diagnosis of lead exposure. Urinary lead excretion reflects the plasma lead concentration, which increases and decreases more rapidly than does blood lead concentration.

Nonspecific laboratory criteria consistent with lead toxicity include normochromic or microcytic anemia, basophilic stippling of RBC on peripheral smear, increased urinary ALA, and coproporphyrin. Liver transaminases may be elevated in acute intoxication. Low-molecular-weight proteinuria and enzymuria may precede elevations in serum creatinine. Radiopacities on abdominal radiograph may be evidence of lead in the GI tract following recent ingestion. This is especially true for lead-based ceramic glazes.

Management

Acute lead encephalopathy is a medical emergency that requires intensive care and monitoring of the patient. Prompt consultation with a toxicologist should be obtained to assist in the management. Because up to 25% of the children who survive an acute episode of encephalopathy sustain permanent CNS damage [22], medical treatment should be instituted before its onset. It has long been recommended that any child who is symptomatic from lead poisoning or has a whole blood lead concentration >80 μg per dL should be hospitalized immediately and treated as a medical emergency [22]. More recently, the Centers for Disease Control and Prevention has issued a statement that children with blood lead concentrations of 70 μg per dL or greater require immediate chelation therapy [23].

Although present-day recommendations for the treatment of lead encephalopathy were derived from experiences in managing children [22,24–26], they have been extrapolated to adults. The basic treatment plan consists of supportive measures and the use of chelating agents. As
with any potential life-threatening emergency, assessment and aggressive management of the airway, breathing, and circulation should be paramount.

Gastrointestinal decontamination, beginning with gastric lavage, is indicated following acute ingestion of virtually any lead-containing substances because even small quantities of paint chip or a sip of lead-containing glaze may contain several hundred milligrams of lead. The use of activated charcoal has been suggested; however, its efficacy is unknown. Abdominal radiograph may reveal radiopaque foreign bodies in the GI tract following recent ingestion of lead-containing substances such as paint chips, lead weights, and lead-based ceramic glazes. Whole bowel irrigation with polyethylene glycol solution has been suggested as a means of decontaminating the GI tract when the presence of lead is evident on radiographic examination of the abdomen. The effectiveness of WBI can be followed by serial abdominal radiographs. Although it is important to eliminate the source of continued lead absorption, therapy should not be delayed by attempts at GI decontamination, especially in cases of encephalopathy. Ultimately, the chief priority is to identify and eradicate the source of lead exposure and institute control measures to prevent repeated intoxication. In addition, other possibly exposed persons should be promptly evaluated.

Lead-containing buckshot, shrapnel, or bullets in or adjacent to synovial spaces should be surgically removed if possible, especially if associated with evidence of systemic lead absorption.

In a child presenting with encephalopathy, immediate treatment should begin with establishing an adequate urine output [22]. This can be accomplished by intravenous (IV) infusion (10 to 20 mL per kg) of 10% dextrose in water during 1 to 2 hours. If this fails to produce a urine output, infusion of a 20% mannitol solution (1 to 2 g per kg) is recommended at 1 mL per minute. Once urine output has been established, IV fluids should be restricted to the calculated basal water and electrolyte requirements plus a careful assessment of continuing losses. An indwelling Foley catheter should be used to monitor the rate of urine formation. IV fluids should be adjusted hourly in order to maintain urine flow that is within the basal metabolic limits, which is 0.35 to 0.50 mL of urine secreted per calorie metabolized per 24 hours or 350 to 500 mL/m²/24 hours. Such management is designed to avoid excessive fluid administration and prevent further development of cerebral edema. Severe lead encephalopathy can occur without cerebral edema [24]. However, when cerebral edema occurs in the presence of encephalopathy,
there is further insult to the brain, and it may be the immediate cause of
death. Children with encephalopathy may exhibit syndrome of
inappropriate antidiuretic hormone [26].

If paralysis with sedation or general anesthesia is required for
controlling seizure activities, a bedside electroencephalogram should be
obtained to rule out electrical status. Because high doses of phenytoin
and phenobarbital were often required to control the initial seizures in
lead encephalopathy, paraldehyde was formerly used. However,
barbiturates were recommended in the prevention of seizures during the
early convalescent phase of lead encephalopathy. Repeated seizures and
hypoxia can exacerbate cerebral edema, and so it was suggested that
anticonvulsants be administered when there is evidence of increased
muscle tone or muscle twitching; one should not wait for obvious seizure
activity [22].

Computed tomography scan of the head should be performed in
patients presenting with encephalopathy to screen for cerebral edema. If
there is evidence of cerebral edema, intracranial pressure (ICP)
monitoring may be indicated and neurosurgical consultation is
recommended. Avoid performing a lumbar puncture when there is
increased ICP associated with cerebral edema. Measures advocated to
control cerebral edema and increased ICP include careful sedation and
neuromuscular paralysis, elevation of the head of the bed,
hyperventilation, restriction of fluid therapy, ventricular drainage,
diuretics (e.g., mannitol or furosemide), and steroids. These measures are
“borrowed” from the neurosurgical experience in managing increased
ICP. Restriction of fluids, the use of mannitol, and hypertonic saline have
been discussed previously. Maintaining the arterial partial pressure of
carbon dioxide between 25 and 30 mm Hg by controlled hyperventilation
has been shown to result in cerebral vasoconstriction and reduced ICP.
The benefit of glucocorticoids for treating perifocal vasogenic edema due
to an intrinsic intracranial mass lesion is well established. However,
glucocorticoids have not been proved beneficial in models of intracellular
cytotoxic edema, and neurologic outcome studies do not support the
routine use of glucocorticoids following head injury, global brain
ischemia, or cerebral vascular accidents [27]. If the cerebral edema
associated with lead encephalopathy is believed to be vasogenic in origin,
the empiric use of dexamethasone should be considered. Surgical
attempts to relieve ICP by flap craniotomy have not been shown to be
beneficial. However, ventricular drainage (via the intracranial bolt placed
for ICP monitoring) may effectively reduce increased ICP.

Chelating agents have been shown to decrease blood lead
concentrations and increase urinary lead excretion. Chelation has also
been associated with improvement in symptoms and decreased mortality.
However, controlled clinical trials demonstrating therapeutic efficacy is
lacking, and treatment recommendations have been largely empiric. Although there appears to have been a sharp reduction in pediatric mortality due to acute lead encephalopathy with the advent of chelation treatment, there were concomitant advances in the management of elevated ICP, and the decline in mortality cannot necessarily be attributed to the use of chelation alone. BAL and calcium disodium edetate (CaEDTA) are the two chelators used in the treatment of lead encephalopathy. DMSA is used for less severe poisoning.

BAL increases both fecal and urinary excretion of lead. It is distributed widely throughout all body tissues, including the brain and RBCs. Because BAL is excreted in the urine and to some extent in the bile, patients with renal failure are not precluded from the use of BAL, whereas patients with hepatic insufficiency may have a lower tolerance to BAL [28]. Details regarding the use of this agent are discussed in the “Arsenic” section of this chapter. BAL and medicinal iron can form a toxic complex that is a potent emetic, and accordingly the treatment of anemia with iron should be delayed until BAL therapy has been completed. If severe anemia requires prompt intervention during chelation therapy, transfusion would be preferable.

CaEDTA enhances the elimination of lead and, to a lesser extent, the elimination of endogenous metals (e.g., zinc, manganese, iron, copper). Increased urinary lead excretion begins within 1 hour and is followed by a decrease in whole blood lead concentration over the course of treatment. CaEDTA diffuses rapidly and uniformly throughout the body, but it does not appear to enter RBCs and very slowly diffuses across the blood–brain barrier [29]. CaEDTA mobilizes lead (primarily) from soft tissues and from a fraction of the larger lead stores present in bone. CaEDTA is not metabolized; rather, it is cleared from the body by urinary excretion. It can be administered intravenously (IV) or intramuscularly (IM), with the former being the preferred and most effective route. Oral administration of CaEDTA has been shown to increase absorption of lead from the GI tract; therefore, it should not be given by this route. The principal toxic effect of CaEDTA is on the kidneys, which can result in renal tubular necrosis. The renal toxicity is dose related and reversible. Because CaEDTA increases renal excretion of lead and its accumulation increases the risk of nephrotoxicity, anuria would be a contraindication in its use. An adequate urine flow should be established before initiating CaEDTA therapy.

In the management of patients with lead encephalopathy, some clinicians advocate the use of BAL and CaEDTA beginning with a priming dose of BAL at the same time that an adequate urine output is being established. The priming dose of BAL is 75 mg per m² (3 to 5 mg per kg) IM and is administered every 4 hours. After 4 hours have elapsed since the priming dose of BAL, a continuous slow IV infusion of CaEDTA 1,500
mg/m²/d (30 mg/kg/d) is started. For cases where there is evidence of cerebral edema and/or increased ICP associated with encephalopathy, CaEDTA (same dosage) should be given by deep IM injection in two to three divided doses every 8 to 12 hours. When the IM route is preferred, procaine (0.5%) should be given along with CaEDTA because IM administration of CaEDTA is extremely painful. BAL and CaEDTA are usually continued for 5 days. For patients with high body lead burdens, cessation of chelation is often followed by a rebound in blood lead concentrations as bone stores equilibrate with lower soft-tissue concentrations. A second course of chelation may be considered on the basis of whole blood lead concentration after 2 days of interruption of BAL and CaEDTA treatment, and the persistence or recurrence of symptoms. A third course may be required if the whole blood concentration rebounds to 50 mg per dL or greater within 48 hours after the second chelation treatment. If chelation is required for the third time, it should begin a week after the last dose of BAL and CaEDTA.

In the management of symptomatic patients with lead poisoning who are not overtly encephalopathic, most clinicians advocate the same course of treatment as for those with encephalopathy, but with lower doses of BAL and CaEDTA. The priming dose of BAL is 50 mg per m² (2 to 3 mg per kg) IM and is administered every 4 hours. After 4 hours have elapsed since the priming dose of BAL, a continuous slow IV infusion of CaEDTA 1,000 mg/m²/d (20 to 30 mg/kg/d) is started. Alternatively, CaEDTA may be given in two to three divided doses every 8 to 12 hours by continuous infusion or deep IM injection. BAL and CaEDTA should be continued for 5 days with daily monitoring of whole blood lead concentrations. BAL may be discontinued any time during these 5 days if the whole blood lead concentration decreases to <50 μg per dL, but CaEDTA treatment should continue for 5 days. A second or third course of chelation may be considered on the basis of the same guidelines as discussed in the previous paragraph.

In the management of asymptomatic patients with whole blood lead concentrations 70 μg per dL or greater, some clinicians would advocate the use of BAL and CaEDTA in the same doses and with the same guidelines as for treatment of symptomatic lead poisoning without encephalopathy. A second course of chelation with CaEDTA alone may be necessary if the whole blood lead concentration rebounds to 50 μg per dL or more within 5 to 7 days after chelation has ceased; some clinicians prefer the use of DMSA.

A water-soluble analog of BAL, DMSA enhances the urinary excretion
of lead, mercury, and arsenic. It has an insignificant effect on elimination of the endogenous minerals calcium, iron, and magnesium. Minor increases in zinc and copper excretion may occur. Oral DMSA is rapidly but variably absorbed, with peak blood concentrations occurring between 1 and 2 hours. The drug is predominantly cleared by the kidneys, with peak urinary elimination of the parent drug and its metabolites occurring between 1 and 4 hours. DMSA is approved for use for lead and mercury intoxications, in which it is associated with increased urinary excretion of the metals, and concurrent reversal of metal-induced enzyme inhibition. Oral DMSA is comparable to parenteral CaEDTA in decreasing whole blood lead concentration during treatment. Although treatment with DMSA has been associated with subjective clinical improvement, controlled clinical trials demonstrating therapeutic efficacy have not been reported. Reported adverse drug events of DMSA include GI disturbances (anorexia, nausea, vomiting, and diarrhea), mercaptan-like (sulfur) odor to the urine, rashes, mild-to-moderate neutropenia, and mild, reversible increases in hepatic transaminases.

Although DMSA is FDA approved for use only in children with whole blood concentration in excess of 45 μg per dL, it has similar ability to lower whole blood lead concentration in adults. Treatment is initiated at an oral dose of 10 mg per kg (350 mg per m²) every 8 hours for 5 days. Treatment is then continued at the same dose every 12 hours for an additional 2 weeks. An additional course of treatment may be considered on the basis of posttreatment whole blood lead concentrations and the persistence or recurrence of symptoms. Whole blood lead concentration may decline by more than 50% during treatment, but patients with large body burdens may experience rebound to within 20% of pretreatment concentrations as bone body stores reequilibrate with tissue concentrations. An interval of two or more weeks may be indicated to assess the extent of posttreatment rebound in whole blood lead concentration. Experience with oral DMSA in severe lead intoxication (e.g., lead encephalopathy or lead colic) is very limited, and consideration should be given to parenteral chelation therapy in such cases.
MERCURY

Mercury (Hg) is a naturally occurring metal that is mined chiefly as mercuric sulfate (HgS) in cinnabar ore. It is converted into three primary forms, each with a distinct toxicology: elemental (Hg⁰) mercury, inorganic (mercurous [Hg⁺¹] and mercuric [Hg²⁺]) mercury salts, and organic (alkyl and phenyl) mercury. The pattern and severity of toxicity are highly dependent on the form of mercury and route of exposure, mostly because of different pharmacokinetic profiles.

Elemental Mercury

Elemental mercury is the only metal that exists in liquid form at standard temperature and pressure. As such, metallic mercury can evaporate slowly at room temperature or rapidly when heated, and can contribute to the partial pressure of the ambient air that is breathed. A small spill in an enclosed space (e.g., a bedroom) can also produce high concentrations of mercury in the air because of its high vapor pressure. Various instruments contain elemental mercury including thermometers, manometers, barometers, switches, pumps, and special surgical tubes (such as Miller–Abbott, Canter, and Kaslow). Dental amalgam is prepared with elemental mercury and contains approximately 50% elemental mercury by weight.

Personnel in occupational settings who are potentially exposed include chlor-alkali mercury cell operation workers, electroplaters, explosives manufacturers, laboratory personnel, pesticide/fungicide production and application workers, manufacturers of batteries or mercury vapor lamps, metallurgists, and miners and processors of cinnabar, gold, silver, copper, and zinc. Exposure to mercury vapor from elemental mercury spill, work hazard, home gold ore purification, accidental heating of metallic mercury, and vacuum cleanup of a mercury spill have also been reported [30].

Pharmacology

When ingested, elemental mercury is poorly absorbed (<0.01%) from the healthy, intact, and normal-functioning GI tract. In contrast, inhaled mercury vapor is believed to cross the alveolar membranes rapidly because of its high diffusibility and high lipid solubility. About 75% of the inhaled dose is retained [31]. The absorbed elemental mercury vapor rapidly diffuses into the RBCs, where it undergoes oxidation to the mercuric ion and binds to ligands in the RBC. However, a certain amount
of the dissolved vapor persists in the plasma to reach the blood–brain barrier, which it crosses readily. Once in the brain tissue, the dissolved mercury vapor is oxidized to mercuric ion, trapping it within the CNS, where it is available for binding tissue ligands. Elemental mercury vapor is also easily transported across the placenta.

Elemental mercury vapor is eliminated from the body mainly as mercuric ion by urinary and fecal routes. Exhalation of mercury vapor and secretion of mercuric ions in saliva and sweat do occur and contribute to the elimination process. The rate of excretion is dose dependent. Elemental mercury follows a biphasic elimination rate, initially rapid and then slow, with a biologic half-life in humans of about 60 days.

Mercuric ion has an affinity to bind and react with sulfhydryl moieties of proteins, leading to nonspecific inhibition of enzyme systems and pathologic alteration of cellular membranes.

The pulmonary and central nervous systems bear the brunt of the insult for elemental mercury vapor poisoning. Damage to the respiratory system results from acute inhalation exposure to high concentrations of elemental mercury vapor, which acts as a direct airway irritant and a cellular poison [30,32]. Pulmonary toxicity is characterized by exudative alveolar and interstitial edema, erosive bronchitis and bronchiolitis with interstitial pneumonitis, and desquamation of the bronchial epithelium. The ensuing obstruction can result in alveolar dilatation, interstitial emphysema, pneumatocele formation, pneumothorax, and mediastinal emphysema.

In the CNS, a cumulative toxic effect occurs as the inhaled elemental mercury vapor is oxidized to mercuric ion, leading to progressive CNS dysfunction. As would be expected, CNS toxicity is typically the result of chronic elemental mercury vapor exposure.

**Clinical Toxicity**

The ingestion of elemental mercury usually causes no adverse effects. However, systemic absorption of mercury is possible in the presence of any bowel abnormality affecting mucosal integrity or impeding normal motility and transit. In addition, inflammatory bowel disease or enteric fistula allowing for prolonged elemental mercury exposure and the conversion of metallic mercury to an inorganic ion has been reported. Elemental mercury that is retained in the appendix can result in local inflammation, perforation, and the consequent possibility of systemic
mercury intoxication. Signs of appendiceal inflammation or systemic mercury absorption and toxicity should be appropriately monitored and treated. Prophylactic appendectomy in the absence of signs and symptoms of appendicitis should be avoided because of the risk of mercury extravasation through the surgical anastomosis and intra-abdominal suppurative complications [33].

Subcutaneous injection of elemental mercury may cause a local fibrous reaction, local abscess, granuloma formation, and systemic embolization, and systemic absorption with toxic manifestations.

Intravenously injected elemental mercury has been reported to cause pulmonary and systemic mercury embolization, associated with an elevated blood mercury concentration, and sequelae may include tremor, lower extremity weakness, and reduced carbon monoxide diffusing capacity. Mercury extravasation at the injection site can produce a severe local inflammatory reaction. Granuloma formation with fibrosis and inflammation with systemic mercury absorption has also been reported.

Acute intense inhalation of mercury vapor in a confined or poorly ventilated space may result in death. Initial symptoms usually occur within several hours following exposure and include fever, chills, headache, dyspnea, gingivostomatitis, nausea, vomiting, metallic taste in the mouth, paroxysmal cough, tachypnea, chest tightness, diarrhea, and abdominal cramping [32]. These symptoms may subside or, in severe cases, may progress to interstitial pneumonitis, bilateral infiltrates, atelectasis, noncardiogenic pulmonary edema, interstitial pulmonary fibrosis, and death. In addition, complications such as subcutaneous emphysema, pneumomediastinum, and pneumothorax may occur. Children younger than 30 months seem to be particularly susceptible to such exposures.

Although aspiration of elemental mercury may cause no acute respiratory symptoms, it may cause cough and mild dyspnea, acute pneumonitis, or progressive cough with copious amounts of frankly bloody sputum production, leading to respiratory compromise and death [34]. Most patients remain asymptomatic or recover without any significant sequelae. In two cases, systemic absorption of the aspirated elemental mercury was suggested by elevations in the 24-hour urinary mercury concentrations, but neither patient became symptomatic. Elemental mercury was consistently evident on chest radiographs obtained on follow-up examination, which varied from 1 month to 20 years. One case with postmortem findings from the lungs 22 years later included globules of elemental mercury surrounded by extensive fibrosis and granuloma formation. Subclinical changes in peripheral nerve function and renal function have been reported, but symptomatic neuropathy and nephropathy are rare.
Diagnostic Evaluation

Diagnosis depends on integration of characteristic findings with a history of known or potential exposure, and the presence of elevated whole blood mercury concentration and urinary mercury excretion. Abdominal radiographs may be used to document the extent of the GI contamination following elemental mercury ingestion. Radiographs of the injection site may help to define the extent of the infiltrated mercury. Chest radiograph and computed axial tomography scan may be useful in determining the location of systemic embolization.

Whole blood and urinary mercury concentrations are useful in confirming exposure. In most people without occupational exposure, whole blood mercury concentration is less than 2 μg per dL and “spot” or single-voided urine mercury concentration is less than 10 μg per L. A quantitative 24-hour urinary mercury excretion, usually less than 50 μg per 24 hours, is probably the most useful tool in diagnosing acute exposure (Table 112.3).

Management

Any patient requiring hospitalization because of acute elemental mercury inhalation or aspiration should be admitted to the ICU. As with any potential life-threatening emergency, assessment and aggressive management of the airway, breathing, and circulation should be paramount. Treatment is primarily supportive. Another priority is to identify and eradicate the source of elemental mercury exposure and to
identify and evaluate other possibly exposed persons.

In cases for which elemental mercury ingestion has been documented, WBI with polyethylene glycol electrolyte solution or surgical removal may be necessary, depending on radiographic evidence of mercury retention, elevated blood urine mercury concentrations, and the patient’s clinical status. Repeat abdominal radiographs may be used to document the effectiveness of WBI or to follow the progress of the ingested metallic mercury.

Aggressive local wound management of the injection site(s) should include prompt excision of all readily accessible subcutaneous areas in which metallic mercury is demonstrated, copious saline irrigation to remove metallic mercury droplets, and suction removal of the mercury [35]. Surgical excision of mercury granulomas has also been recommended. Injection of BAL into the wound is not recommended as it may delay wound healing.

Patients acutely exposed to elemental mercury vapor should be monitored closely for respiratory symptoms. Chest radiographs, arterial blood gases, and pulmonary function should be followed in symptomatic patients. Oxygen and bronchodilators should be administered as needed. Progressive deterioration of respiratory function may require aggressive airway management with tracheal intubation, mechanical ventilation, and positive end-expiratory pressure. Early treatment with corticosteroids has been used in an attempt to reduce the complication of pulmonary fibrosis. However, neither corticosteroids nor prophylactic antibiotics have proved to be beneficial in the management of elemental mercury vapor–induced pulmonary complications.

Patients who have aspirated elemental mercury should be managed in a similar fashion. Vigorous suctioning, postural drainage, and good pulmonary toilet may assist the patient in expectorating some of the aspirated mercury. In addition, bronchoscopy may be indicated.

Chelating agents that are commercially available in the United States for use in the treatment of mercury poisoning include BAL, DMSA, and d-penicillamine (see the “Arsenic” and “Lead” sections). The choice of chelator depends on the form of mercury involved and the presenting signs and symptoms of the patient. DMSA and d-penicillamine may facilitate the absorption of mercury from the GI tract and should not be given when there is evidence of mercury present in the gut. Because animal studies show that BAL may redistribute mercury to the brain from other tissue sites [36–38] and the brain is a target organ in elemental mercury poisoning, it would seem prudent not to use BAL for the
treatment of inhalational exposures. DMSA appears to be associated with fewer adverse events and more efficient mercury excretion when compared with D-penicillamine and is preferred for mercury vapor poisoning. DMSA may enhance urinary mercury excretion and reduce nephrotoxicity after GI absorption of elemental mercury. The initial recommended dose of DMSA is 10 mg per kg every 8 hours, tapering to every 12 hours during the next several days. DMSA can be administered via nasogastric tube in severe poisoning cases in which endotracheal intubation is required.

The therapeutic end points of chelation are poorly defined. Probably the only objectively measurable effectiveness of chelation therapy is enhanced urinary excretion of mercury. A potential end point for chelation may be when the patient’s urinary mercury concentration approaches normal. Although the use of chelators is recommended to increase excretion and relieve target organs of metal burden, the use of BAL has not been proved to affect the course of elemental mercury–induced respiratory failure, and the effect of DMSA on clinical outcome has not yet been fully studied.

There does not appear to be a role for multiple-dose activated charcoal, hemoperfusion, or hemodialysis in removing elemental mercury.

**Inorganic Mercury**

Acute inorganic mercury poisoning is usually the result of intentional or accidental ingestion. Most of the literature on inorganic mercury poisoning deals with mercuric chloride (mercuric bichloride [HgCl₂]), with the lethal adult dose estimated to be between 1 and 4 g.

Mercurials are available in medications (antiparasitic, antihelminthic, vermifuge, antiseptic, antipruritic, and disinfectant), paints, stool fixatives, permanent-wave solutions, teething powder, button batteries, fungicides/biocides, folk remedies (Mexican American treatments for “empacho,” a chronic stomach ailment; Asian, particularly Chinese, herbal or patent medications), and occult practices (Latin American and Caribbean natives). Although mercurial medications have largely been replaced by less toxic drugs, topical antiseptics containing mercury are still being used.

**Pharmacology**

Absorption of inorganic mercury salt from the GI tract is probably dose dependent. After absorption, the salt dissociates into the ionic form and is initially distributed between RBCs and plasma. Distribution of mercury within the body and within the organs varies widely. It has been demonstrated by animal autoradiographic study that mercuric ion is...
accumulated predominantly in the renal cortex. Mercury ions do not appear to significantly cross the blood–brain barrier or the placental barrier. However, on the basis of the autoradiographic study, the brain does take up mercury slowly and retains it for a relatively longer period of time [39]. Mercury ions are eliminated from the body mainly by the urinary and fecal routes. The rate of excretion is dose dependent. Inorganic mercury follows a biphasic elimination rate, initially rapid and then slow, with a biologic half-life of about 60 days in humans.

Mercury ions have an affinity to bind and react with sulfhydryl moieties of proteins, leading to nonspecific inhibition of enzyme systems and pathologic alteration of cellular membranes. In addition, inorganic mercurials are highly corrosive substances.

The target organs of inorganic mercury poisoning are the GI tract and kidneys. The caustic property of the inorganic mercurials could potentially cause damage throughout GI tract, including corrosive stomatitis, necrotizing esophagitis, gastritis, and ulcerative colitis. A report of postmortem examination of patients who died within 48 hours postingestion showed severe hemorrhagic necrosis of the upper GI wall. Acute oliguric renal failure and uremia may result from acute tubular necrosis of the distal portions of the proximal convoluted tubules [40,41]. The CNS is usually spared because only small amounts of mercuric ion can cross the blood–brain barrier. However, cases of CNS toxicity have been described with chronic mercury ingestion.

**Clinical Toxicity**

The clinical effects of acute inorganic mercury poisoning can be divided into the initial local corrosive effect on the GI tract, followed by the injury that occurs at the site of excretion, which are the kidneys.

Inorganic mercury is a highly caustic substance. Depending on the amount ingested, the GI symptoms that follow may vary from mild gastritis to severe necrotizing ulceration of the intestinal mucosa, which can be fatal within a few hours. Ingestion of 100 mg of inorganic mercury has been reported to be associated with a bitter metallic taste in the mouth, a sense of constriction about the throat, substernal burning, gastritis, abdominal pains, nausea, and vomiting. Abrupt onset of hematemesis, hemorrhagic gastroenteritis, and abdominal pain are expected following a serious acute ingestion, and intestinal necrosis may ensue. In addition, massive bleeding from the colon has been reported as late as 8 to 9 days postingestion. Most of the bleeding came from the rectum, which was the most severely involved section of the colon. Such injuries to the GI tract can lead to massive fluid, electrolyte, and blood loss, resulting in shock and death.
Acute inorganic mercury ingestion may lead to acute oliguric renal failure. Invariably, those patients who develop renal involvement initially have severe GI symptoms. Typically, oliguric renal failure occurs within 72 hours postingestion, and, as such, the initial GI symptoms may be resolving although renal toxicity ensues. Spontaneous resolution of acute toxic anuria with renal tubular regeneration may be expected to occur between 8 and 12 days [42], with clinical recovery (if it occurs) between 9 and 14 days. Chronic exposure may result in CNS toxicity.

**Diagnostic Evaluation**

Diagnosis depends on integration of characteristic findings with a history of known or potential exposure and presence of elevated whole blood mercury concentration and urinary mercury excretion. Inorganic mercury may be visualized on an abdominal radiograph as radiopaque foreign bodies in the GI tract. A positive radiograph would support the diagnosis, but a negative one would not exclude it.

Whole blood and urinary mercury concentrations (see “Elemental Mercury” section) are useful in confirming exposure. Whole blood mercury concentration >50 μg per dL in acute inorganic mercury poisoning is often associated with gastroenteritis and acute renal tubular necrosis.

**Management**

General management considerations are the same as for elemental mercury poisoning. In patients with acute ingestion, GI decontamination should be performed as soon as possible to minimize absorption and decrease the corrosive effect of the ingested inorganic salt. As with the ingestion of any corrosive substance, inducing emesis is to be discouraged. Elective tracheal intubation may be prudent before attempting GI decontamination. Gastric lavage should be performed with caution as the GI tract may have already been severely damaged. Endoscopy is recommended if corrosive injury (drooling, dysphagia, and abdominal pain) is suspected. Although theoretically reasonable but not rigorously studied, the use of a protein gastric lavage solution (1 pint of skim milk with 50 g of glucose, 20 g of sodium bicarbonate, and 3 eggs beaten into a mixture) to bind the mercury has been suggested, along with rinsing the stomach with egg white or concentrated human albumin after the lavage [41]. Activated charcoal may be considered as 1 g of charcoal is capable of binding 850 mg of mercuric chloride.

In cases in which there is radiographic evidence of radiopaque foreign
bodies in the GI tract and if there is no evidence of gastroenteritis, WBI with polyethylene glycol electrolyte solution should be considered. Repeat abdominal radiographs may be used to document the effectiveness of WBI.

Gastrointestinal injury may result in severe fluid, electrolyte, and blood loss, and attention should be given to monitoring the patient’s volume status. Replace intravascular and GI losses by the appropriate administration of crystalloids, colloids, and blood products. An indwelling Foley catheter should be placed to carefully monitor the urine output, which should be maintained at 2 to 3 mL/kg/h. It is important to distinguish between oliguria due to inadequate volume resuscitation and oliguria due to toxic nephropathy resulting in renal failure. Invasive hemodynamic monitoring may be necessary.

It should be remembered that inorganic mercury is a highly corrosive substance. Aggressive surgical intervention may be required in cases in which there is severe gastric necrosis or when hemorrhagic ulcerative colitis becomes life threatening. It has been suggested that the rectum should be resected at the time of colectomy when it is indicated for controlling hemorrhage from the colon [40].

British anti-Lewisite and DMSA (see “Arsenic” and “Lead” sections) are the chelating agents of choice. The effectiveness of BAL depends on the promptness of its administration and the administration of an adequate dose. BAL is most effective if given within 4 hours of ingestion [43]. Prompt intervention is paramount in reducing renal injury, and so expedient chelation therapy would be prudent in suspected cases of acute inorganic mercury poisoning. Chelation should not be withheld while waiting for laboratory confirmation of mercury poisoning. DMSA is also effective, but the capacity of the GI tract to absorb orally administered DMSA may be very much impaired in cases of severe inorganic mercury poisoning when hemorrhagic gastroenteritis, hemodynamic instability, and splanchnic edema are present. Once the GI and cardiovascular status has been stabilized, chelation with DMSA may be substituted for BAL.

Once renal damage has occurred from inorganic mercury poisoning, therapy should be directed at the acute renal failure that may ensue. Hemodialysis should be used to support the patient through the oliguric or anuric renal failure period. A potential problem arises with continued BAL therapy in patients who develop renal insufficiency because the kidneys are one of the main routes by which BAL-Hg is eliminated. In such circumstances, BAL therapy may be judiciously continued as there is some evidence from animal studies that a significant fraction of BAL-Hg is also excreted in the bile. Some studies suggest hemodialysis may contribute to the elimination of BAL-Hg in patients with renal failure. For a patient who has renal failure but is otherwise stable and has a functional GI tract, DMSA is an alternative to BAL.
Organic Mercury

The organomercurials are compounds in which the mercury atom is joined to a carbon atom via a covalent bond. It is the relative stability of this covalent bond that determines the toxicology of the organic mercury compounds. The organomercurials can be classified as short-chain alkyl (methyl-, ethyl-, and propylmercury), long-chain alkyl, and aryl (phenyl) mercury compounds. In general, the short-chain alkyl group, particularly methylmercury, is considered the most toxic. Acute ingestion of 10 to 60 mg per kg of methylmercury may be lethal, and chronic daily ingestion of 10 μg per kg may be associated with adverse neurologic and reproductive effects.

Potential sources of exposure to organic mercury include herbicide, fungicide, germicide, and timber preservative. In the general population, the major source of exposure to methylmercury is through the consumption of predacious fish (e.g., pike, tuna, swordfish). Major incidents of human poisoning with methylmercury have occurred (Minamata and Iraq epidemics) with devastating outcomes.

Pharmacology

Organic mercury antiseptics undergo limited skin penetration; however, in rare cases, such as topical application to an infected omphalocele, dermal absorption can occur.

Methylmercury is well absorbed after inhalation, ingestion, and probably dermal exposure. It is widely distributed throughout the body. In the blood, more than 90% is found in the RBCs, with whole blood–to–plasma ratios of 200:1 to 300:1 [44]. Methylmercury is present in the body as water-soluble complexes mainly attached to thiol ligands and is highly mobile. It enters the endothelial cells of the blood–brain barrier as a specific complex with L-cysteine. This L-cysteine complex is structurally similar to the large neutral amino acid L-methionine and is carried across the cell membrane on the large neutral amino acid carrier [45]. Methylmercury is transported out of mammalian cells as a complex with reduced glutathione and is secreted into bile as a glutathione complex. The glutathione moiety is degraded in the bile duct and gallbladder and finally to the L-cysteine complex. It is reabsorbed and returned to the liver, thereby completing the enterohpatic cycle [46]. In humans, about 10% of the body’s methylmercury burden is in the CNS and the biologic half-life of methylmercury is 45 to 70 days. Methylmercury readily passes the blood–brain barrier as well as the placenta barrier. In animal studies, the dissociation between the carbon and mercury bond of methylmercury is very slow [44], and phenylmercury undergoes rapid breakdown to inorganic mercury within 24 hours. In humans, the major route of
excretion of methylmercury is in the feces, with less than 10% appearing in the urine. Extensive enterohepatic recirculation in the GI tract has been demonstrated to occur with methylmercury [47].

Mercury has an affinity to bind and react with sulfhydryl moieties of proteins, leading to nonspecific inhibition of enzyme systems and pathologic alteration of cellular membranes. The CNS is particularly vulnerable to the toxic effects of methylmercury and is a potent teratogen and reproductive toxin. Methylmercury has been shown to alter brain ornithine decarboxylase, an enzyme associated with cellular maturity, and neurotransmitter uptake at the pre- and postsynaptic adrenergic receptor sites.

Clinical Toxicity

Most of the detailed information regarding toxicity has been derived from methylmercury poisoning cases. Methylmercury is a cumulative poison, primarily affecting the CNS. There does not appear to be a distinct difference between acute and chronic methylmercury poisoning. Following acute methylmercury intoxication, symptoms are usually delayed for several weeks or months. The classic triad of methylmercury poisoning is dysarthria, ataxia, and constricted visual fields [48]. Other signs and symptoms include paresthesias, hearing impairment, progressive incoordination, loss of voluntary movement, and mental retardation. Perinatal exposure to methylmercury has caused mental retardation and a cerebral palsy type of syndrome in offspring. Ethylmercury compounds may also cause gastroenteritis. Phenylmercury compounds produce a pattern of toxicity intermediate between alkyl and inorganic mercury.

Diagnostic Evaluation

Diagnosis depends on integration of characteristic findings with a history of known or potential exposure, and presence of elevated whole blood mercury concentration, which may reflect recent exposure. Whole blood mercury concentrations greater than 20 μg per dL have been associated with symptoms. Hair concentrations have been used to document remote exposure. Urinary mercury concentrations are not useful.

Management
General management considerations are the same as for elemental mercury poisoning. Following acute ingestion of organic mercurials, gastric lavage should be performed. Administration of activated charcoal may be of benefit. A successful way to increase the rate of methylmercury excretion is to introduce a nonabsorbable mercury-binding substance (polythiol resin) into the GI tract so as to interrupt the enterohepatic recirculation of methylmercury [49,50]. Repeated oral administration of a polythiol resin in methylmercury intoxication may be beneficial.

Limited data suggest that oral neostigmine may improve motor strength in patients with moderate-to-severe chronic methylmercury intoxication. DMSA is the preferred chelating agent. BAL appears to be ineffective in treating neurologic signs and symptoms of methylmercury poisoning. In addition, animal studies show that BAL may redistribute mercury to the brain from other tissue sites [36–38]. In contrast, DMSA was effective in reducing the brain concentration of methylmercury, and DMSA prevented the development of cerebellar damage in methylmercury-poisoned animals [51]. However, in humans, the effect of DMSA on clinical outcome has not yet been fully studied.

Hemodialysis is of little value because methylmercury has a large volume of distribution, and a considerable amount of methylmercury resides within the RBCs.
REFERENCES

Hydrocarbons are a group of organic compounds composed primarily of hydrogen and carbon. Although often mixtures, hydrocarbons may be divided into four basic types: aliphatic, halogenated, aromatic, and terpene.

Hydrocarbon exposures are frequent and account for an inordinate number of health care visits and hospital admissions. The American Association of Poison Control Centers reported 32,551 hydrocarbon exposures in 2015 [1]. Twenty-five percent were seen in a health care facility, and there were 18 deaths. Nearly 30% of total exposures occurred in children younger than 6 years of age and involved ingestions, and most of these were accidental. Almost 5% of the fatalities in this age group were related to hydrocarbons during the year of this report [1].

Storage in unmarked, readily accessible containers and an attractive color or aroma account for the high percentage of exposures in young children. In adolescents and adults, poisoning generally results from inhalational abuse, occupational exposure, intentional ingestion, or accidental aspiration during the siphoning of fuels. Cutaneous and even intravenous exposures have also been described. Intentional ingestions by adults usually involve larger volumes, and there is a much greater likelihood of other coingested drugs or toxins. The majority of deaths are caused by intentional inhalational abuse.

ALIPHATIC HYDROCARBONS

Aliphatic hydrocarbons, known as petroleum distillates, are straight-chain compounds produced from the fractional distillation of natural petroleum (Table 113.1). They are the most common cause of hydrocarbon poisoning.
After ingestion, the major toxicity of petroleum distillates is their potential to cause a fulminant, and sometimes fatal, chemical pneumonitis. Aspiration of even small amounts may produce severe pulmonary toxicity. Although vomiting often precedes and precipitates aspiration, lack of vomiting does not preclude the possibility that aspiration has occurred. Little or no systemic toxicity occurs even with
intragastric administration of large doses (12 to 18 mL per kg) [2].

The risk of aspiration increases with lower viscosity, lower surface tension, and higher volatility. Viscosity, the tendency to resist flow, is the most important property determining aspiration potential [3]. Substances with low viscosity (e.g., gasoline, mineral seal oil, and kerosene) have a high aspiration potential, whereas those with high viscosity (e.g., mineral oil and fuel oil) have a lower potential for aspiration. Reduced surface tension may also allow a substance to spread rapidly from the upper gastrointestinal (GI) tract to the trachea. High volatility (tendency of a liquid to become a gas) increases the likelihood of pulmonary absorption.

Aspirated petroleum distillates inhibit the function of surfactant, resulting in alveolar collapse, ventilation–perfusion mismatch, and subsequent hypoxemia. In addition, bronchospasm and direct capillary damage lead to a chemical pneumonitis and hemorrhagic bronchitis–alveolitis [3,4]. In animals exposed to kerosene, acute alveolitis peaked at 3 days and resolved by 10 days [4]. Histologically, a chronic proliferative process occurred, peaking at 10 days and resolving over several weeks. When highly viscous petroleum distillates are aspirated, a less inflammatory, more localized, and indolent lipoid pneumonia may occur [5].

Following ingestion of aliphatic hydrocarbons, central nervous system (CNS) manifestations result principally from hypoxia and acidosis caused by pulmonary toxicity [6]. Although systemic toxicity is uncommon, it may be seen if the petroleum distillate is a vehicle for more toxic substances (e.g., heavy metal and pesticide), if it contains additives, or if a concomitant or massive ingestion has occurred [7]. Cardiovascular, hepatic, renal, and hematologic toxicities depend on the specific toxic substance involved.

Use of aliphatic hydrocarbons as volatile substances of abuse (VSA) is a serious and growing problem. It is most often seen in adolescents who use VSA as an easily available, legal, and affordable substitute for other intoxicants [8]. The most common aliphatic VSA are \( n \)-hexane, \( n \)-butane, isobutane, and propane—seen in adhesives, aerosols, liquefied petroleum gas (i.e., cigarette lighter refills and camp stoves), and gasoline.

Inhalation may involve sniffing, “huffing” (spraying the solvent onto a cloth held to the mouth and nose), “bagging” (spraying the solvent into a paper or plastic bag and repeatedly inhaling the vapors), or a variant of these techniques [8]. These highly lipid-soluble substances are rapidly absorbed through the lungs and distributed to the CNS and fatty tissues.
The onset of symptoms occurs in seconds to minutes, with peak effects occurring somewhat later owing to slower diffusion into tissues. Elimination of aliphatic hydrocarbon VSA is primarily by pulmonary excretion, and successive oxidation and metabolism by hepatic cytochrome P450 mixed-function oxidases [9].

Aliphatic VSA toxicity includes acute and chronic neurologic dysfunction; asphyxia; cardiovascular abnormalities; and pulmonary, GI, and cutaneous irritation. CNS toxicity ranges from stimulation at initial or low doses to a depressant effect, with general inhibition of cortical function at high doses [10]. Peripheral neuropathy and irreversible CNS damage have been reported [11,12]. Inhaled aliphatic hydrocarbons are asphyxiants (as well as pulmonary irritants) and may cause hypoxemia by decreasing the concentration of oxygen in inspired air. Their arrhythmogenic effects are thought to be owing to their potentiation of endogenous catecholamines (cardiac sensitization), which may promote dysrhythmias (e.g., ventricular tachycardia or fibrillation) [13]. Additional factors such as hypoxia, acidosis, electrolyte abnormalities, and underlying cardiac conditions may contribute to arrhythmias. Dermal and mucosal irritation is due to their ability to dissolve lipids after prolonged or high-dose exposure [14]. Deaths associated with inhalational abuse may result from coma with respiratory depression, aspiration, or injuries incurred while intoxicated as well as from cardiac arrhythmias [15].

**Clinical Manifestations**

The clinical course after the ingestion of petroleum distillates primarily depends on the presence or absence of concomitant aspiration and its severity. The patients who aspirate generally demonstrate symptoms within 30 minutes; those who do not have symptoms within 6 hours will remain asymptomatic [16]. Presenting signs and symptoms usually involve three main organ systems: pulmonary, CNS, and GI. Cardiovascular, renal, hematologic, and cutaneous toxicity have also been reported [16,17]. In most cases, symptoms resolve during the next 2 to 5 days with supportive care [16,17].

Initial coughing, gasping, and choking may progress and peak during the first 24 to 48 hours to tachypnea with grunting respirations, nasal flaring, retractions, and cyanosis [7,16]. The odor of petroleum distillates may be apparent on the breath. Wheezing, rhonchi, and rales may be heard on auscultation. In severe cases, pulmonary edema and hemoptysis occur. Arterial blood gases may demonstrate hypoxemia from ventilation–perfusion mismatch and early hypocarbia, which progresses to hypercarbia and acidosis. Abnormalities on chest radiographs occur in up to 75% of hospitalized patients, appearing within 2 hours in 88% of
the patients and 12 hours in 98% [7,16], but may be delayed up to 72 hours. Early radiographic abnormalities include unilateral, but more commonly bilateral, basilar infiltrates and fine punctate perihilar densities. Localized areas of atelectasis are often present, whereas pleural effusions, pneumatoceles, and pneumothoraces occur infrequently [18]. Pneumatoceles generally occur 3 to 15 days after ingestion and resolve during 15 days to 21 months [19]. Radiographic findings correlate poorly with clinical symptoms and may persist for several days to weeks after symptoms have resolved [18,19]. Asymptomatic patients may have abnormal chest radiographs, whereas symptomatic patients may have minimal or no radiographic abnormalities early in the course [7].

Within the first 24 to 48 hours, fever (38°C to 39°C) and leukocytosis are common [16]. The persistence of fever beyond 48 hours suggests bacterial superinfection.

CNS involvement may occur in those with aspiration-induced hypoxemia, large intentional ingestions, or ingestions of mixtures that contain other toxic agents (e.g., aromatic hydrocarbons). Symptoms range from dizziness and lethargy (91%) to somnolence (5%) and, rarely, coma (3%) and convulsions (1%) [7]. The severity of CNS dysfunction often correlates with the severity of aspiration.

GI symptoms, such as local irritation of the oropharynx (e.g., burning), nausea, vomiting, and abdominal pain, are commonly reported. Hematemesis and melena occur rarely [7]. Vomiting appears to increase the likelihood of aspiration [20]. Cardiovascular toxicity is uncommon, but dysrhythmias and sudden death after gasoline siphoning have been reported [13,14].

Inhalation abuse may result in a range of acute CNS manifestations, including dizziness, incoordination, restlessness, excitement, euphoria, confusion, hallucinations, slurred speech, and coma with respiratory depression [10,11]. Peripheral neuropathy has been reported after chronic exposure [11]. Pulmonary toxicity may present as respiratory distress with cyanosis, or syncope with tachycardia or bradycardia. GI irritation may cause nausea, vomiting, and abdominal pain. Dermatologic manifestations range from perioral frost or pigmentation (after direct inhalation from a container) to local skin irritation [7].

Cases of acute renal tubular necrosis [21], hemoglobinuria secondary to intravascular hemolysis [22], severe burns after prolonged immersion in gasoline [23], and supraglottitis [24] have been reported. Aliphatic hydrocarbons are highly flammable, especially gasoline, and accidental thermal burns may occur during recreational use [25]. Therefore, the patients with unexplained burns should be questioned regarding possible inhalation abuse. Chronic leaded gasoline inhalation may also be accompanied by organolead poisoning [26]. Parenteral administration of petroleum distillates has caused local cellulitis, thrombophlebitis, and
necrotizing myositis, with resultant compartment syndromes. Associated systemic effects include febrile reactions, hemorrhagic pneumonitis, pulmonary edema, seizures, and CNS depression [27,28].

Diagnostic Evaluation

After ingestion, diagnostic evaluation includes a thorough history (e.g., identity, amount, and concentration of toxin; time of ingestion; and symptoms before presentation at health care facility) and a physical examination (focusing on vital signs and the respiratory, CNS, and GI systems). Pulse oximetry should be monitored and a chest radiograph obtained in all symptomatic patients and in cases in which aspiration is suspected. In symptomatic patients or those who have ingested concomitant toxins or toxic additives, laboratory evaluation should include an arterial blood gas determination; complete blood cell count; electrolyte, blood urea nitrogen, creatinine, and glucose measurements; liver function tests; and a urinalysis.

Management

The patients with ingestions who remain or become asymptomatic with a normal chest radiograph (obtained 2 hours or more after exposure) may be discharged after 6 hours of observation. All symptomatic patients, those with abnormal chest radiographs, arterial blood gases, or pulse oximetry, and the patients with suicidal intent should be hospitalized. Gastric decontamination is not recommended in petroleum distillate ingestion because absorption and systemic toxicity are minimal, and spontaneous or induced vomiting increases the risk of aspiration and pneumonitis [29]. Gastric decontamination is recommended only if potentially toxic amounts of aromatic or halogenated hydrocarbons, pesticides, heavy metals, or other substances have been ingested within 1 to 2 hours or if time of ingestion is unknown and there are no contradictions. Ipecac syrup is not recommended for GI decontamination. The patients who are unconscious, unable to protect the airway (e.g., poor or absent gag reflex), or deteriorating should be intubated with a cuffed endotracheal tube and then have gastric aspiration or lavage performed. Activated charcoal and cathartic are indicated only if a toxic additive is present or concomitant ingestion has occurred. If cutaneous exposure has occurred, contaminated clothing should be removed cautiously and the skin thoroughly washed with soap and water [7].
All patients with respiratory symptoms should be given oxygen, placed on a cardiac monitor, and have intravenous access established. An arterial blood gas determination and chest radiograph should be obtained. The need for intubation should be based on clinical assessment of respiratory distress and objective data from arterial blood gases or pulse oximetry. Chest radiographs do not always correlate with clinical status and should not be used as the sole determinant for respiratory interventions. Noninvasive ventilation may be helpful for maintaining oxygenation, and the patient should be carefully monitored for the development of a pneumothorax. Bronchospasm should be treated with β2-agonist bronchodilators [13].

Supportive care of pneumonitis includes careful monitoring of acid–base, fluid, and electrolyte balance (e.g., cautious hydration to avoid pulmonary edema), serial arterial blood gases or pulse oximetry, and chest radiograph evaluation. Complete blood cell counts with differential, sputum, or tracheal aspirate Grams stains and cultures can assist in determining if bacterial superinfection has occurred. Baseline renal and liver function studies and a toxic screen should be obtained if toxic additives or concomitant ingestion is suspected. Animal and clinical investigations have failed to demonstrate any beneficial effect of steroid treatment [30]. Two animal studies indicate that they may be harmful [31,32]. In addition, prophylactic antibiotics have not been shown to be helpful [31]. Fever and leukocytosis secondary to chemical pneumonitis are common during the first 24 to 48 hours in the absence of superimposed bacterial pneumonia [7]. Antibiotics should be given only to patients with documented bacterial pneumonias (based on Gram stain with culture of sputum or tracheal aspirate results) or worsening chest radiograph, leukocytosis, and fever after the first 40 hours [7]. Successful use of high-frequency percussive ventilation and extracorporeal membrane oxygenation for the treatment of respiratory failure has been reported [33–35]. Other measures such as cardiopulmonary bypass, partial liquid fluorocarbon ventilation, and exogenous surfactant have been suggested for refractory cases, but the data to support their use are limited [36].

Most patients with petroleum distillate poisoning recover fully with supportive care. Because minor pulmonary function abnormalities have been detected in as many as 82% of the patients with aspiration pneumonitis who subsequently become asymptomatic [37], follow-up care with pulmonary function testing should be considered. When appropriate, the patient should receive psychiatric evaluation and poison-prevention education before final disposition.
HALOGENATED HYDROCARBONS

Halogenated hydrocarbons are aliphatic and aromatic derivatives that contain one or more atoms of chlorine, bromine, fluorine, or iodine. Although dozens of halogenated hydrocarbons are currently recognized, relatively few account for the majority of the toxic exposures. Like the aliphatic agents, halogenated hydrocarbons pose an aspiration risk. However, they are more readily absorbed from the GI tract and can cause systemic toxicity, most notably of the CNS, cardiovascular system, and hepatic and renal systems.

Halogenated hydrocarbons are used in the household and industry. They are frequently used as solvents, degreasers, dry-cleaning agents, refrigerants, aerosol propellants, and fumigants. Toxic exposures occur most commonly through inhalation, and several halogenated hydrocarbons (e.g., trichloroethylene, methylene chloride, and fluorocarbons) are intentionally inhaled for recreational purposes [11]. Bagging and huffing have been associated with a number of solvent-abuse deaths.

After absorption from the GI tract and occasionally through the skin, halogenated hydrocarbons are concentrated in adipose tissue, liver, and kidney. Metabolism and elimination vary according to the individual substance, with most undergoing at least some excretion through the lungs as unchanged parent compound and nearly all undergoing some degree of metabolism in the liver, with subsequent excretion of metabolites by the lungs and/or kidneys. Carbon tetrachloride (CCl₄), methylene chloride, and trichloroethane are prototypes of this class.

Carbon Tetrachloride

Previously used as a dry-cleaning agent and antihelminthic, CCl₄ is now restricted to industrial use, primarily in the production of refrigerants, aerosol propellants, and solvents. It is well absorbed through the skin [38], lungs, and GI tract, and it is concentrated in adipose tissue [39]. Approximately 50% of an absorbed dose is excreted unchanged by the lungs. Most of the remainder is metabolized by the liver to reactive intermediates or free radicals, or both, which covalently bind to proteins and induce lipid peroxidation, resulting in hepatocellular damage [40]. Ethanol, methanol, and isopropyl alcohol all increase CCl₄ hepatotoxicity, presumably through enzyme induction [41]. At lower doses, fatty degeneration of the liver occurs; at higher concentrations, centrilobular necrosis results [42]. In addition to hepatic damage, CCl₄ produces acute
tubular necrosis of the kidney, affecting the proximal tubules and Henle’s loop. Although a direct nephrotoxic effect is likely [43], volume contraction may contribute to renal failure in some patients [44]. Inhalation exposure to CCl₄ may produce symptoms ranging from mild CNS depression to coma and death [45]. Although the estimated lethal dose of orally ingested CCl₄ is 90 to 100 mL, deaths have occasionally been reported after much smaller doses.
